Statistical modelling of resolved debris discs

DISSERTATION

zur Erlangung des akademischen Grades

Doctor Rerum Naturalium (Dr.rer.nat)

vorgelegt dem Rat der Physikalisch-Astronomischen Fakultät

der Friedrich-Schiller-Universität Jena

von M.Sc. Nicole Pawellek

geboren am 06. Dezember 1988 in Meiningen

Erster Gutachter:

Prof. Dr. Alexander Krivov
Astrophysikalisches Institut und Universitätssternwarte
Friedrich-Schiller-Universität Jena

Zweiter Gutachter:

Prof. Dr. Sebastian Wolf
Institut für theoretische Physik und Astrophysik
Christian-Albrechts-Universität Kiel

Dritter Gutachter:

Prof. Dr. Jean-Charles Augereau
Institut de Planétologie et d'Astrophysique de Grenoble (IPAG)
Grenoble, France

Tag der öffentlichen Verteidigung: 17. November 2016

Gewidmet dem Wissenschaftsoffizier der Enterprise.

Danksagung

Auf dem Weg zu meiner Promotion haben mich zahlreiche Menschen begleitet und unterstützt, ohne die die vorliegende Dissertation nicht möglich gewesen wäre. Allen voran möchte ich mich bei meinem Doktorvater, Professor Alexander „Sascha“ Krivov, bedanken, der mir zu jeder Zeit mit Rat und Tat zur Seite stand und immer einen rettenden Einfall hatte. Ohne seine montäglichen Anrufe wäre es kein Montag gewesen. Des Weiteren danke ich Dr. Katharina Schreyer, Dr. Torsten Löhne, Herrn Christian Schüppler, Dr. Christian Vitense, Dr. Martin Reidemeister und Herrn Fabian Geiler für die vielen produktiven Diskussionen, wie auch Frau Monika Müller, Dr. Frank Gießler und Herrn Jürgen Weiprecht für die technische und bürokratische Unterstützung. Auch die Kollegen von anderen Instituten, wie Dr. Attila Moór, Dr. Steve Ertel, Dr. Jonathan Marshall und Dr. Benjamin Montesinos, waren mir mit ihrem Wissen und ihren Ideen eine große Hilfe. Nicht zuletzt möchte ich mich bei meinen Physik- und Mathematiklehrern, Herrn Wolfgang Fiedler, Frau Bianca Krämer, Dr. Winfried Zappe und Dr. Eberhard Koch bedanken, die ihre Begeisterung für die Astronomie und Physik auf mich übertragen haben.

Neben der fachlichen Unterstützung dürfen natürlich auch nicht die vielen anderen Menschen vergessen werden, die mir einen Ausgleich zum Arbeitsalltag geschaffen haben. Zunächst sei meiner Familie gedankt, besonders meinen Eltern Kerstin und Frank, die mich bereits in jungen Jahren zur Astrophysik gebracht und das gesamte Studium überhaupt erst ermöglicht haben. Mein Bruder Markus erklärte mir die Grundlagen des Programmierens und meine Großeltern Ingrid und Alfred sorgten dafür, dass ich immer mit ausreichend Essen versorgt war. Ohne meine Musiklehrer, Frau Ingeborg und Herr Christian Glöckner, die mich von frühester Kindheit an unterrichtet haben, sowie Herr Martin Meier und Frau Regine Seifert, die später dazu kamen, wäre ich vermutlich an mancher Stelle verzweifelt und so möchte ich auch sie alle an dieser Stelle erwähnen. Ebenso bin ich dankbar für die guten Freunde, die immer ein offenes Ohr für meine Probleme hatten: Anne und Oliver Schwartz und Katrin Richter sowie die Mitwirkenden bei den sonntäglichen Andachten: Schwester Kati, Herr Klaus Genieser, Frau Maria Glöckner-Latour und Frau Marita Krüger.

Kurzfassung

In dieser Arbeit wurde eine Stichprobe von 39 räumlich aufgelösten Trümmerschreibe um AFGKM-Sterne mit der Absicht untersucht, Korrelationen zwischen den Zentralsternparametern der Trümmerschreibensysteme und den Scheibenparametern an sich zu finden. Eine Hürde war dabei die Entartung zwischen den Staubeilchengrößen und der Entfernung des Staubes vom Zentralstern. Kleine Partikel in einer großen Entfernung lieferten ähnliche Ergebnisse wie große Teilchen näher am Stern. Jedoch konnten durch die räumliche Auflösung der Scheiben deren Radien mittels einer neuen Methode bestimmt und so die Entartung gebrochen werden. Die gewählte Stichprobe stellt die bis dato größte analysierte Sammlung von räumlich aufgelösten Scheiben dar, wobei die Modellierung der spektralen Energieverteilung (SED) die Grundlage der Analyse bildete.

Es wurden zwei verschiedene Modelle für die Anpassung der SEDs genutzt, zum einen der modifizierte Schwarzkörper (MBB) und zum anderen die Staubgrößenverteilung (SD). Der Vergleich der beiden verdeutlichte, dass sie zu ähnlichen Korrelationen der verschiedenen Parameter führen, jedoch auch Unterschiede bei individuellen Scheiben sichtbar sind. Da die Teilchengröße und die Staubsorte ebenfalls entartet sind, wurden fünf verschiedene Staubarten für die Modellierung verwendet: reines Astrosilikat und reiner Kohlenstoff sowie Mischungen von Astrosilikat mit Eis, Kohlenstoff und Vakuum. Die Verwendung all dieser Sorten führte ebenfalls zu ähnlichen Korrelationen.

Im Ergebnis zeigte sich, dass die neue Methode der Radienbestimmung auf einen Großteil der Trümmerschreibe anwendbar ist, unabhängig von deren Entfernung oder dem Spektraltyp des Zentralsterns. Des Weiteren wurde eine große Streuung der Radien über den gesamten Bereich der stellaren Leuchtkraft festgestellt. Daher scheint die entgültige Form der Scheibe nicht von temperaturabhängigen Prozessen abhängig zu sein. Unter der Annahme, dass eine Scheibe aus Planck'schen Strahlern besteht, lässt sich ein Schwarzkörperradius ableiten. Die Untersuchung des „wahren“ Scheibenradius im Verhältnis zu diesem Schwarzkörperradius zeigte einen Abfall mit zunehmender stellarer Leuchtkraft, was es nun erlaubt, den Radius von unaufgelösten Trümmerschreibe zu schätzen.

Die Scheibentemperatur zeigt einen Anstieg mit zunehmender stellarer Leuchtkraft, wobei sie in Einheiten der Schwarzkörpertemperatur abnimmt. Die dominante Teilchengröße steigt leicht mit der stellaren Leuchtkraft an, jedoch ist dieser Anstieg auch mit einer konstanten Teilchengröße von $(5 \pm 3) \mu\text{m}$ vereinbar. Die Theorie sagt einen wesentlich steileren Anstieg, bedingt durch den zunehmenden Strahlungsdruck des Zentralsterns, vorher. Dadurch ist ein Abfall der dominanten Teilchengröße in Einheiten der Ausstoßgröße erkennbar, der zudem die stärkste Korrelation dieser Arbeit darstellt und robust gegenüber den verschiedenen Staubsorten und Kollisionsmodellierungen ist. Es wurden mehrere Erklärungen für diesen Abfall untersucht. Neben rein technischen oder statistischen wurden auch physikalische Effekte, wie ein endliches Reservoir an Oberflächenenergie für die kleinsten Staubeilchen und die Rolle der dynamischen Anregung der Scheibe analysiert. Ersterer scheint jedoch nur von untergeordneter Bedeutung zu sein. Letzterer hingegen deutet darauf hin, dass die dynamische Anregung mit der stellaren Leuchtkraft zunimmt. Scheibe um Sterne früherer Spektraltypen könnten daher möglicherweise massereichere Planeten oder Planetesimale besitzen.

1 Introduction and motivation

*“It is difficult to understand the universe
if you only study one planet.”*

based on Miyamoto Musashi (1645)

The science of planetary system formation and evolution is a famous field of interest, since it tries to address the fundamental questions: “What are the origins of Earth (and humankind)?” and “Are we alone in the Universe?”. In the course of time different phenomena were discovered, inspiring the enquiring human mind. These discoveries, beginning with the identification of planets by ancient Greeks and discovery of asteroids in the 19th century after the advent of the telescope, followed by the more recent detection of the Vega phenomenon and protoplanetary discs in the late 20th century and the serendipity of the first exoplanet found around the main-sequence star 51 Peg, help us to better understand the processes and mechanisms that drive the formation and evolution of planets. However, up to now we do not completely understand how a planetary system forms or evolves and thus we would like to contribute to the previous knowledge with this piece of work. Our thesis concentrates on the successors to protoplanetary discs, namely debris discs, which represent leftovers of planet formation and evolution processes. In the following sections we will briefly describe the nature of debris discs and the aims of this work.

1.1 Debris discs

1.1.1 Solar system

In 1766 Johann Titius formulated an empirical equation describing the regular spacing between the orbits of the six known planets at that time. Shortly after, Johann Bode claimed that this equation predicted a planet lying between Mars and Jupiter that had not yet been discovered. Hence, a search for this object started (Bode, 1772) leading to the discovery of the first asteroid (1) Ceres in 1801 (Piazzi, 1802). The first representative of the Asteroid belt was rapidly followed by the discovery of many other similar objects¹. The Asteroid belt is a part of our Solar system’s debris disc which is the successor of a protoplanetary disc. It is an optically thin and gas-poor disc composed of planetesimal belts where colliding and growing solids are situated (Wyatt, 2008; Krivov, 2010). While the smallest dust particles of the debris disc are produced by collisions of planetesimals and are expelled from the system by direct stellar radiation pressure (e.g., Burns et al., 1979; Müller et al., 2010), the larger bodies are more influenced by stellar gravity and other processes such as stirring by planets or Poynting-Robertson drag (e.g., Kenyon and Bromley, 2001; Mustill and Wyatt, 2009). Another fact is that debris discs can be made of one or more distinct material rings. In case of our Solar system the Asteroid belt is the inner ring whereas the Edgeworth-Kuiper-belt (Edgeworth, 1943, 1949; Kuiper, 1951) with its famous dwarf planet Pluto (Leonard, 1930; Tombaugh, 1946) is the outer one. In Figure 1.1 a scheme of a typical planetary system is depicted including terrestrial and giant planets,

¹Today, 713968 asteroids (numbered and unnumbered) are known in the main Asteroid belt. (Yeomans, Donald K.: “JPL Small-Body Database Search Engine”. NASA JPL, retrieved 9th May 2016)

Five Zones of Debris Dust

asteroidal and Edgeworth-Kuiper belt zones as well as a hot dust component close to the host star and a disc halo.

As described above the Asteroid belt is known since the late 19th century, whereas the Edgeworth-Kuiper belt was a theory from the 1940s and 50s (Edgeworth, 1943, 1949; Kuiper, 1951) and only confirmed in the 1990s (Jewitt et al., 1992). Therefore, they were not interpreted as parts of the Solar system’s debris disc at first. The first debris disc known as such was observed around Vega in the 1980s (Aumann et al., 1984).

1.1.2 Investigation methods

Since the large planetesimals – the parent bodies of debris disc dust – possess only a small total cross section they cannot be detected by current observational techniques. Thus, the investigation of dust produced by collisions of these planetesimals is necessary. The total cross section of the small dust particles is much higher compared to the parent bodies and their thermal emission much easier to detect. The observation of dust allows conclusions about the parent body population to be drawn and potentially the indirect detection of planets in the circumstellar system offering insight into planet formation and evolution processes. The study of debris disc spectral energy distributions (SEDs) is among other methods, such as imaging and infrared spectroscopy, an important tool to gather information and will be the basis of this work. SEDs reflect debris disc properties, such as disc temperature, typical dust grain sizes, and the amount of disc material. However, the modelling of them is difficult, since a degeneracy between disc radius and typical dust grain sizes exists (e.g., Krist et al., 2010; Ertel et al., 2011; Churcher et al., 2011b; Löhne et al., 2012; Booth et al., 2013; Morales et al., 2013). That means that large grains at a small distance from the star can produce a similar SED as small grains at a large distance and thus disentangling both, distance from the star and grain size, is not possible. Only resolved discs, such as Fomalhaut (Acke et al., 2012) and β Pictoris

(Vandenbussche et al., 2010) offer a solution, since their radii could be derived from images.

Over the last years the frequency of discs was studied by several groups (e.g., Su et al., 2006; Eiroa et al., 2013; Chen et al., 2014; Thureau et al., 2014; Marshall et al., 2016). Eiroa et al. (2013) found that nearly 20% of FGK-stars own a debris disc, whereas Thureau et al. (2014) analysed more luminous A-stars of which approximately 24% possess a disc. These results do not mean that more discs can be found around A-stars than around K-stars, since the frequencies are statistically indistinguishable (Trilling et al., 2008; Eiroa et al., 2013). Furthermore, the structure of discs was investigated. As known from our Solar system, debris discs might not only possess Edgeworth-Kuiper belts, but also Asteroid belts. Thus it is not surprising that a recent study of Spitzer/IRS mid-infrared spectra (Chen et al., 2014) revealed that nearly 66% of known debris discs seem to be confined into two rings, similar to the Solar system. To the present day nearly 100 discs could be resolved in one way or another (e.g., MacGregor et al. (2015); Choquet et al. (2016), Table C.1) and so the large number of discs offers a possibility for statistical analyses and the search for correlations between different debris disc parameters derived from SED modelling and stellar parameters, such as stellar luminosity or temperature.

1.2 Aims of this work

In this work we will investigate a sample of 39 resolved debris discs and their SEDs, breaking the degeneracy of disc radii and typical dust grain sizes, in order to find correlations between disc and stellar properties. This will allow conclusions about system parameters of unresolved discs to be made, providing a deeper insight in the disc physics and formation and evolution processes.

The dust size distribution and therefore the typical grain size will be of special interest here. As Krivov et al. (2000) stated, several processes influence the size distribution. Besides radiation pressure and collisions, transport processes and erosion mechanisms (Wyatt et al., 2011) play an important role. Hence, the derived size distribution allows conclusions about these processes. When the size distribution is steep enough (which is the case for most of the discs), particles just above a certain minimum grain size are the most abundant and thus carry the largest part of the particle cross section. As a matter of fact, these particles are easy to detect in thermal emission in mid- and far infrared and can be referred to as particles with a typical dust grain size. Grains smaller than the radiation pressure blowout limit are expelled and it is expected that the typical grain size is close to this limit. The ratio of minimum grain size and blowout limit is influenced by the dynamical excitation of the dust producing planetesimals, as shown by dynamical simulations. If the average eccentricity of the dust parent planetesimals is low, meaning that the disc is dynamically cold, the ratio is expected to be much larger than unity (e.g., Thébault and Wu, 2008; Krivov et al., 2013). On the other hand, for high dynamical excitation, the ratio should be slightly above unity (e.g., Krivov et al., 2006; Thébault and Augereau, 2007). Thus, the grain size ratio allows conclusions not only about the dynamical excitation itself but about processes that alter it, e.g., stirring by planets or planetesimals. Of course, the typical grain size depends on other parameters besides the dynamical excitation as well. The dust properties, both optical and mechanical, the disc radius and the system's age are only a few examples for that. So if the disc is spatially resolved and the systems age could be inferred from the host star, conclusions about dust properties will be possible.

We will begin this thesis in Chapter 2 with the question of how a debris disc can be described and will explain the basic terms used for that, e.g., fractional luminosity or blowout grain size. Since the modelling of SEDs is an essential part here as well, a short introduction into the technical aspect of SED fitting is given in Chapter 3. Then it is discussed which resolved debris discs are appropriate for a statistical analysis (Chapter 4) and how their radii can be derived (Chapter 5). This is followed by

a presentation of the fitting results (Chapter 6) whereas a detailed analysis of the grain size – stellar luminosity trend is given in Chapter 7. The trend found between disc-to-blackbody radius ratio and stellar luminosity is investigated in Chapter 8. A summary can be found in Chapter 9.

2 Theoretical foundations

At the beginning of this work we would like to concentrate on the question how a debris disc can be observed, described and analysed. Therefore, we will start with an introduction to spectral energy distributions, which are the basis of our debris disc analysis. Then an explanation of the basic terms of a debris disc system such as blowout grain size or fractional luminosity will follow. This chapter will end with the description of the statistical methods used for analysing a sample of debris discs.

2.1 Spectral energy distributions

A debris disc is composed of gas, dust and planetesimal belts. While the gas component may be a remnant of the predeceasing protoplanetary disc (Moór et al., 2013b) the circumstellar dust is short-lived and thus the existence of dust-producing planetesimals is evident. The disc material is confined to rings which contain growing and crushed solid material with sizes ranging from several tens of kilometres (planetesimals) to sub-micrometres (dust) (e.g., Stern, 1996; Sitko et al., 1998; Thébault et al., 2003; Greaves et al., 2004; Fitzgerald et al., 2007). The micron sized dust particles can most

Figure 2.1: Flux density as a function of wavelength for HD 21997 (Moór et al., 2013b). Black solid line shows emission of stellar photosphere. Red filled circles with error bars show observational measurements.

effectively be traced by their thermal emission and therefore it is not astonishing that the first debris disc was found by the so-called infrared excess emission in the spectral energy distribution (SED) (Aumann et al., 1984). This infrared excess is indeed the common evidence for the presence of a debris disc and thus the SED is the basis for any debris disc analysis and needs to be explained in more detail. In Figure 2.1 a typical infrared excess is shown. Obviously, the flux density of the circumstellar system measured at infrared wavelengths is higher than what is expected from the star alone. In order to describe this emission physically we will begin with an explanation of the optical parameters of dust

particles. This is followed by an introduction of different radiation models starting with blackbody radiation.

2.1.1 Optical parameters of dust particles

Different radiation processes occur in a debris disc, namely absorption, reemission and scattering of stellar radiation by the dust grains. The basics of these processes were treated by Bohren and Huffman (1983) using Mie theory and here the most important parameters will be explained.

Figure 2.2: Optical efficiency factors as explained by Burns et al. (1979). Black arrows represent directional vectors of electromagnetic waves.

Compact spherical particles with a geometrical cross section A are assumed and in Figure 2.2 such a particle is depicted as a red circle. When an electromagnetic wave with a certain energy approaches the particle it is subject to the above mentioned radiation processes. The parameter Q_{abs} gives the part of the energy which is absorbed, while Q_{sca} represents the part of scattered and Q_{trans} the part of transmitted energy. The scattered part contains a momentum of $Q_{\text{sca}} \times \cos(\theta)$, which is sent in the forward direction. The parameter $\langle \cos(\theta) \rangle$ is the weighted average of the angular dependence of the scattered radiation (Burns et al., 1979) and called the asymmetry factor. It is given by

$$\langle \cos(\theta) \rangle \equiv \int_{4\pi} f(\theta) \cos \theta \, d\Omega, \quad (2.1)$$

where θ is the scattering angle, Ω the solid angle and $f(\theta)$ the phase function computed by Mie theory (Bohren and Huffman, 1983). For the particle with cross section A this means that on an area $C_{\text{abs}} = A \times Q_{\text{abs}}$ the incoming energy will be absorbed while on $C_{\text{sca}} = A \times Q_{\text{sca}}$ it will be scattered. These areas are called the absorption or scattering cross section, respectively. The parameter Q_{pr} is the radiation pressure efficiency. It is defined as

$$Q_{\text{pr}} \equiv Q_{\text{abs}} + Q_{\text{sca}}(1 - \langle \cos(\theta) \rangle). \quad (2.2)$$

If the whole energy were scattered in forward direction, Q_{pr} would be equal to Q_{abs} . In case of perfect back-scattering Q_{pr} would be $Q_{\text{abs}} + 2Q_{\text{sca}}$. And if the energy were scattered isotropically Q_{pr} would be the sum of Q_{abs} and Q_{sca} .

Now we assume a blackbody particle in equilibrium conditions. The energy emitted by the grain must be the same as the absorbed energy. Using Kirchhoff's law of absorption and emission it can be shown that $Q_{\text{abs}} = \text{Emissivity}$ and furthermore $Q_{\text{abs}} \equiv 1$ for a blackbody. Here, Q_{abs} is independent of the wavelength of the electromagnetic wave, but in general all the above mentioned efficiencies are functions of it.

2.1.2 Blackbody radiation

In the last section we saw that blackbodies are ideal absorbers with an absorption efficiency of unity. Thus, the easiest model to describe the emission of the dust particles is the blackbody radiation. This model was first described and derived by Max Planck (Planck, 1900) and is the basis of many debris disc analyses.

Planck's law

The Planck law can be written in terms of wavelength or frequency:

$$B_{\lambda}(\lambda, T)d\lambda = \frac{2 h c^2}{\lambda^5 \left[\exp\left(\frac{h c}{\lambda k T}\right) - 1 \right]} d\lambda, \quad B_{\nu}(\nu, T)d\nu = \frac{2 h \nu^3}{c^2 \left[\exp\left(\frac{h \nu}{k T}\right) - 1 \right]} d\nu. \quad (2.3)$$

Here, ν is the frequency, λ the wavelength, c the speed of light, h the Planck constant, k the Stefan-Boltzmann constant and T the temperature. In the field of debris discs another form of this law is used, since the flux density for a certain frequency interval is measured in units of Jansky ($[Jy] = 10^{-26} \text{W}/(\text{Hz m}^2)$), but the wavelength is a more common and intuitive parameter. Therefore,

$$B_{\nu}(\lambda, T)d\nu = \frac{2 h c}{\lambda^3} \left[\exp\left(\frac{h c}{\lambda k T}\right) - 1 \right]^{-1} d\nu \quad (2.4)$$

is often used. At long wavelengths the Planck curve can be reduced to the Rayleigh-Jeans approximation given by

$$B_{\nu}^{\text{RJ}}(T)d\nu = \frac{2\nu^2}{c^2} kT d\nu = \frac{2kT}{\lambda^2} d\nu. \quad (2.5)$$

Modified blackbody radiation

In order to describe the infrared excess emission first found around Vega and therefore called the Vega phenomenon, Backman and Paresce (1993) developed the modified blackbody (MBB) as a model for thermal emission by dust grains. They assumed a constant absorption efficiency $Q_{\text{abs}} = 1$ up to a certain critical wavelength λ_0 . For wavelengths larger than λ_0 the absorption efficiency decreases with $(\lambda/\lambda_0)^{-\beta_{\text{mod}}}$, where β_{mod} is the opacity index. This leads to

$$B_{\nu}^{\text{mod}}(\lambda, T) = B_{\nu}(\lambda, T) \left[H(\lambda_0 - \lambda) + H(\lambda - \lambda_0) \left(\frac{\lambda}{\lambda_0} \right)^{-\beta_{\text{mod}}} \right] \quad (2.6)$$

as the resulting blackbody function and

$$Q_{\text{abs}}(\lambda, s) = \begin{cases} 1, & \lambda \leq \lambda_0 \\ (\lambda/\lambda_0)^{-\beta_{\text{mod}}}, & \lambda > \lambda_0 \end{cases}, \quad (2.7)$$

as the function of the absorption efficiency, where s represents the grain size and $H(\lambda)$ the Heaviside step function. The wavelength λ_0 can be interpreted as a kind of characteristic grain size. Backman and

Paresce (1993) stated that depending on the grain optical properties $\lambda_0 = 2\pi s$ for strongly absorbing materials. For weakly absorbing materials the relation turns out to be $\lambda_0 = s/(2\pi)$ and for moderate absorbing material $\lambda_0 = s$ is a good approximation. Nevertheless, information on the dust material can also be inferred from the parameter β_{mod} . While a value of ~ 1 should be appropriate for amorphous materials, a value of ~ 2 represents crystalline materials or metals (Witt, 1989). A value of ~ 1.5 was found to characterise the grains in the interstellar medium (ISM) (e.g., Planck Collaboration et al., 2015).

2.1.3 Mie radiation

The blackbody description of the dust emission is simple, but it only treats dust particles in an idealised way. In reality, the dust grains have an absorption efficiency that as described above depends on the emission wavelength, the grain size and the optical indices (e.g., refractive indices) of the dust material. Thus, it is necessary to know the composition of dust and the grain sizes in order to get a more physical approach to the dust modelling.

Spectra of debris discs reveal solid features arising from different dust compositions (e.g. Chen et al., 2006; Lisse et al., 2007; Fujiwara et al., 2012, 2013; Donaldson et al., 2013; Riviere-Marichalar et al., 2014; Mittal et al., 2015). Nevertheless, the composition of dust (volume fractions of each component) remains unknown in most of the cases since solid state features are only present in debris disc systems with hot dust emitting in the infrared (Matthews et al., 2014b). This work concentrates on the three most often detected compositions, namely silicate, carbon and water ice and several mixtures of them.

Astronomical silicate

Draine and Lee (1984) proposed the artificially generated material *astronomical silicate* or *astrosilicate* which is one of the most prominent dust compositions describing the emission of the ISM. The basis for this material are lab measurements of crystalline olivine in order to construct a dielectric function. This function is used to derive the optical parameters (Q_{abs} , Q_{sca} , etc.) of the dust. It was improved over the years by Laor and Draine (1993) and Draine (2003b) who among other things extended the wavelength range used. Figure 2.3 shows the optical parameters Q_{abs} and Q_{sca} for different dust grain

Figure 2.3: Absorption and scattering efficiency as a function of wavelength for astronomical silicate and different dust grain sizes ranging from 0.01 μm to 1000 μm . Red solid line: blackbody conditions; blue dashed line: modified blackbody conditions for $s = 10 \mu\text{m}$ using $\lambda_0 = 2\pi s$ and $\beta_{\text{mod}} = 2.5$.

sizes. The efficiencies decrease with increasing wavelength, whereas for small particles this decrease

starts at shorter wavelengths than for large particles. Large particles have nearly constant values equal to unity, which means that they behave more like blackbodies. A comparison with the MBB model shows that the assumptions of $\lambda_0 = 2\pi s$ and $\beta_{\text{mod}} \sim 2$ for crystalline materials are in good agreement with the slope of Q_{abs} for a grain size larger than $10\text{ }\mu\text{m}$. For smaller particle sizes the absorption efficiency is not as well approximated by the MBB model.

Carbon

Another dust component often used is carbon, many kinds of which exist and different optical parameters are available. In this work the amorphous carbon dust of Zubko et al. (1996) (“ACAR”) is used. Since many debris discs are modelled with this kind of dust (e.g., Donaldson et al., 2013; Lebreton et al., 2012), the modelling results of this work are comparable to them. The optical parameters of car-

Figure 2.4: Same as Figure 2.3, but for amorphous carbon. $\beta_{\text{mod}} = 1.9$.

bon and astronomical silicate look similar as shown in Figures 2.3 and 2.4. In the shorter wavelength range between $0.1\text{ }\mu\text{m}$ and $10\text{ }\mu\text{m}$ the values for Q_{abs} of astronomical silicate are decreasing faster than those for carbon. Furthermore, there is no peak at $\sim 10\text{ }\mu\text{m}$ for the carbon material, since this emission feature is typical for silicate. The MBB approximation is as well in good agreement with the depicted shape of Q_{abs} for particles larger than $10\text{ }\mu\text{m}$. The opacity index is smaller compared to astrosilicate what was expected for amorphous materials (Witt, 1989), however it is larger than unity.

Water ice

The third component used in this work is water ice proposed by Li and Greenberg (1998). Here, the dust particles are assumed to have a silicate core with a layer of H_2O dominated ice accreted in dense molecular clouds (Greenberg, 1978). Figure 2.5 reveals that between $0.1\text{ }\mu\text{m}$ and $1\text{ }\mu\text{m}$ the ice particles have a very small $Q_{\text{abs}} \sim 10^{-10}$. This means that the grains do not absorb much energy in this wavelength area. But the decrease of Q_{abs} with increasing wavelength can be seen here as well, although it begins at longer wavelengths ($\sim 100\text{ }\mu\text{m}$). Compared to astrosilicate and carbon the absorption efficiency of water ice shows many peaks at several wavelengths and therefore its shape is not as smooth as for the other two materials. Hence, a comparison to the MBB approximation is difficult. However, Greenberg (1978) stated that water ice is a moderately absorbing material and thus $\lambda_0 = s$ was used for illustration.

Figure 2.5: Same as Figures 2.3-2.4. MBB conditions: $\lambda_0 = s = 10 \mu\text{m}$ and $\beta_{\text{mod}} = 1.3$.

Mixtures

To generate the optical parameters of the mixtures used in this work the Bruggeman (1935, 1936) mixing rule was applied. Its advantage against other mixing rules is that it treats each component in the same way and not as environmental part or inclusional part. It is completely symmetric. Since the volume fractions of dust components in debris discs are not known, they were equally distributed in the mixtures. The dust compositions used in this work are given in Table 2.1.

Table 2.1: Dust compositions and their bulk densities.

Dust composition	ρ [g/cm ³]
50% astrosilicate + 50% vacuum	1.65
50% astrosilicate + 50% ice	2.25
100% astrosilicate	3.30
50% astrosilicate + 50% carbon	2.63
100% carbon	1.95

Dust grain temperatures

As said before, the absorption efficiency depends on the wavelength and the dust grain size (see Figures 2.3 - 2.5). The general shape of Q_{abs} with increasing wavelength stays the same, but there are differences for the dust compositions used. As a consequence of that, not only the temperatures of the grain sizes vary, but also the temperatures of same sized particles of different compositions do (see Figure 2.6). For the calculation of the temperature the balance of absorbed stellar radiation and thermal reemission is assumed (Equations 2.25-2.27). Obviously, grains with a size smaller than $10 \mu\text{m}$ are warmer than blackbody, while particles of approximately $10 \mu\text{m}$ have temperatures close to the blackbody temperature. Between a size of $0.1 \mu\text{m}$ and $1 \mu\text{m}$ lie the hottest particles. Grains smaller than $0.1 \mu\text{m}$ or larger than $1 \mu\text{m}$ are colder (Krivov et al., 2006).

In Figure 2.7 the temperature of the dust grains is given as a function of grain size and disc radius. The wavelength λ_0 can be interpreted as a grain size. Since astronomical silicate is a strongly absorbing material the relation $\lambda_0 = 2\pi s_{\text{min}}$ is assumed. The temperature isolines of MBB and SD method show a different behaviour. While for MBB particles the temperature increases with decreasing grain size,

Figure 2.6: Left: absorption efficiency as a function of wavelength for different dust compositions. The particle used has a grain size of $s = 1 \mu\text{m}$. right: dust grain temperature $T_d(s)$ for a star with $1L_\odot$ at a radius of 100 AU for different dust compositions. T_{BB} is the blackbody temperature.

the smallest SD grains ($s = 0.1 \mu\text{m}$) turn out to be cooler than grains with a size of $s = 0.5 \mu\text{m}$, which was explained already in Figure 2.6. It is obvious as well that grains with a certain size are warmer closer to the star than grains farther out.

Figure 2.7: The temperature of dust particles as a function of characteristic grain size and disc radius. Left: modified blackbody, right: size distribution. Solid lines show temperature isolines for 30 K (black), 60 K (yellow), 100 K (cyan), 150 K (pink) and 300 K (blue).

2.2 Disc parameters

After having a look at SEDs and optical parameters of dust, it is now necessary to introduce key parameters of a debris disc system. Without these the modelling of a SED would not be possible. Therefore, we will explain the most common terms.

2.2.1 Basic definitions

Dust particles in a debris disc are distributed in several ways. On the one hand they are size distributed, meaning that there is a certain number $N(s)$ of grains with a certain grain size s . On the other hand,

the particles have a spatial distribution as well. At a distance r from the star a certain number of grains, $N(r)$, exists. Debris discs are optically thin and thus, the thermal emission of all particles irrespective of their position can be seen in the SED. Therefore, no conclusions about the azimuthal or vertical distribution can be drawn. Thus, the disc is assumed azimuthally symmetrical with no vertical extension while the particles have a size and a radial distribution, $N(r, s)$.

Surface number density $N(r, s)$

The surface number density, $N(r, s)ds$, represents the number of dust particles in an annulus per total area of the annulus and per grain size interval $[s, s + ds]$. The easiest assumption for $N(r, s)$ is a power law for both, the radial distribution and the grain size distribution with the shape

$$N(r, s) = N_0 \left(\frac{r}{R_0} \right)^{-p} \left(\frac{s}{s_0} \right)^{-q}, \quad (2.8)$$

where N_0 , R_0 and s_0 are arbitrary normalisation parameters for the number of particles, the radius and the grain size, while p and q are the radial distribution index or the size distribution index, respectively. Using the geometrical optical depth τ , the parameter N_0 can be calculated with

$$\tau = \frac{A}{A_{\text{disc}}} = \frac{A}{\pi(R_{\text{max}}^2 - R_{\text{min}}^2)} = \frac{2\pi}{R_{\text{max}}^2 - R_{\text{min}}^2} \int_{R_{\text{min}}}^{R_{\text{max}}} \int_{s_{\text{min}}}^{s_{\text{max}}} N(r, s) s^2 ds r dr. \quad (2.9)$$

Here, A is the cross section of the dust particles, A_{disc} the area of the disc, R_{min} and R_{max} the inner and outer radius of the disc, and s_{min} and s_{max} certain minimum and maximum grain sizes. Thus, N_0 becomes

$$N_0 = \frac{A(2-p)(3-q)}{2\pi^2 R_0^2 s_0^3} \left[\left(\frac{R_{\text{max}}}{R_0} \right)^{2-p} - \left(\frac{R_{\text{min}}}{R_0} \right)^{2-p} \right]^{-1} \left[\left(\frac{s_{\text{max}}}{s_0} \right)^{3-q} - \left(\frac{s_{\text{min}}}{s_0} \right)^{3-q} \right]^{-1}, \quad (2.10)$$

if $p \neq 2$ and $q \neq 3$ are assumed. In case of $p < 2$ the largest part of the particle cross section, A , is located in the outer region of the disc (closer to R_{max}), while for $p > 2$ it is closer to the inner region. Considering the grain sizes, A is dominated by small particles if $q > 3$, while the large particles contribute more in case of $q < 3$. Assuming the limiting case of $p = 2$ and $q = 3$, the normalisation parameter N_0 changes to

$$N_0 = \frac{A}{2\pi^2 R_0^2 s_0^3} \left[\ln \left(\frac{R_{\text{max}}}{R_{\text{min}}} \right) \ln \left(\frac{s_{\text{max}}}{s_{\text{min}}} \right) \right]^{-1}. \quad (2.11)$$

Here, the dust is equally distributed over the whole annulus and all grain sizes contribute the same fraction to the total cross section.

Dust mass M_{dust}

Knowing the surface number density $N(r, s)$, the dust mass is given by

$$M_{\text{dust}} = \frac{4s_0 A \varrho}{3} \frac{3-q}{4-q} \frac{\left(\frac{s_{\text{max}}}{s_0} \right)^{4-q} - \left(\frac{s_{\text{min}}}{s_0} \right)^{4-q}}{\left(\frac{s_{\text{max}}}{s_0} \right)^{3-q} - \left(\frac{s_{\text{min}}}{s_0} \right)^{3-q}}, \quad (2.12)$$

with ϱ being the bulk density of the grain material and assuming $q \neq 4$. If $q < 4$ the mass is dominated by the largest dust particles, while the smallest particles contribute the most for $q > 4$. In case of $q = 4$ the dust mass is given by

$$M_{\text{dust}} = \frac{4A\varrho}{3} \ln \left(\frac{s_{\text{max}}}{s_{\text{min}}} \right) \left[\frac{1}{s_{\text{min}}} - \frac{1}{s_{\text{max}}} \right]^{-1}, \quad (2.13)$$

and is equally distributed over the whole grain size range, meaning that every size interval contributes the same fraction.

2.2.2 Radiation pressure and blowout grain size s_{blow}

Dust particles in debris discs are subject to several mechanisms, e.g., stellar radiation pressure, which acts to remove dust grains below a certain size from the system, and alters the orbital motion of larger grains by transfer of momentum. In the stellar gravitational field dust particles are attracted to the star while they move in elliptical or circular orbits around it. This motion can be derived from Newton's gravitational law:

$$\vec{F}_G = -\frac{4\pi}{3} s^3 \varrho G M_{\text{star}} \frac{\vec{r}}{r^3}, \quad (2.14)$$

where G is the gravitational constant, M_{star} the stellar mass and \vec{r} the radial vector. On the other hand, the dust is repelled by direct stellar radiation pressure:

$$\vec{F}_{\text{rad}} = \frac{L_{\text{star}} \pi s^2 Q_{\text{pr}}}{4\pi c} \frac{\vec{r}}{r^3}. \quad (2.15)$$

Here, compact spherical particles are assumed. The parameter Q_{pr} is the radiation pressure efficiency averaged over the stellar spectrum and c the speed of light. The radiation pressure efficiency is explained in Section 2.1. Burns et al. (1979) defined the ratio of gravitational force and radiation pressure as β :

$$\beta \equiv \frac{|\vec{F}_{\text{rad}}|}{|\vec{F}_G|} = \frac{3L_{\text{star}}}{16\pi G M_{\text{star}} c} \frac{Q_{\text{pr}}}{\varrho s}. \quad (2.16)$$

This ratio is independent of the distance to the star, r , and since it is proportional to the inverse grain size, $1/s$, it is obvious that for large particles β is small and for small particles β is large. Furthermore, the dependence of $Q_{\text{pr}}(s)$ is neglected. Due to the radial independence of β it is possible to write $\vec{F}_{\text{rad}} = -\beta \vec{F}_G$. The effective “photogravitational force” (Krivov, 2010) is then

$$\vec{F}_{\text{PG}} = \vec{F}_G + \vec{F}_{\text{rad}} = \vec{F}_G (1 - \beta) = -\frac{4\pi}{3} s^3 \varrho G M_{\text{star}} (1 - \beta) \frac{\vec{r}}{r^3}. \quad (2.17)$$

This means that as a result of stellar radiation pressure the particle seems to be attracted by a central object of mass $M_{\text{star}} (1 - \beta)$ instead of the original stellar mass M_{star} .

Now a large planetesimal is assumed for which β is close to zero. It moves around the central star on an elliptical orbit with eccentricity e and semi-major axis a . Its specific orbital energy is then given by

$$E_{\text{pl}} = \frac{v^2}{2} - \frac{GM_{\text{star}}}{r} \equiv -\frac{GM_{\text{star}}}{2a}, \quad (2.18)$$

where v is the planetesimal velocity. If the planetesimal is located at the pericentre, r is given by $r_{\text{pc}} = a (1 - e)$ and the velocity reduces to

$$v_{\text{pc}}^2 = \frac{GM_{\text{star}}}{a} \frac{1 + e}{1 - e}. \quad (2.19)$$

If a small dust grain with a large value of β is released from the planetesimal, due to a collision for instance, it has an orbital energy of

$$E_{\text{grain}} = \frac{v^2}{2} - \frac{GM_{\text{star}}(1 - \beta)}{r} \equiv -\frac{GM_{\text{star}}(1 - \beta)}{2a}. \quad (2.20)$$

To eject this small grain from the circumstellar system, its energy, E_{grain} must be larger than zero. Knowing the grain velocity, which is the same as the planetesimal velocity, and the distance from the star, β is given in the pericentre as

$$\beta \geq \frac{1 - e}{2}. \quad (2.21)$$

If a particle moves on a circular orbit with $e = 0$, the parameter β must be larger than $1/2$ in order to expel the grain from the circumstellar system. Using Equation (2.16), the grain size s corresponding to $\beta = 1/2$ is called the *blowout size* s_{blow} . In this work we will not take into account a possible eccentricity of the parent bodies. Hence, the blowout grain size will always be the grain size for which $\beta = 1/2$. In Figure 2.8 the grain orbits as a function of β are depicted. If this parameter is smaller

Figure 2.8: Particle orbits as a function of β from Krivov et al. (2006).

than $1/2$ the particles stay in bound orbits around the star. In case of $1/2 < \beta < 1$ the grains are ejected on hyperbolic orbits and in case of $\beta > 1$ the ejection orbits will be anomalous hyperbolas.

2.2.3 Collisional evolution

Due to eccentric orbits of the debris mutual collisions are inevitable. Indeed, destructive collisions are a dominant process in known debris disc systems. The relative velocities between two colliding objects need to have a certain minimum level (e.g., Kenyon and Bromley, 2004b; Krivov et al., 2006; Löhne et al., 2008; Thébault and Augereau, 2007; Wyatt et al., 2007b) in order to be destructive. While in protoplanetary discs these relative velocities are damped by the dense ambient gas, in debris discs this damping process is not effective, since these discs are gas-poor. But in order to reach the high velocities necessary for destructive collisions, the low damping is not sufficient. When a protoplanetary disc evolves to a debris disc it loses the primordial gas and the solid particles should preserve the low velocity dispersion they had previously. Hence, some kind of “stirring mechanism” must ignite

the destructive collisions (Wyatt, 2008). One possibility is self-stirring by largest (~ 1000 km sized) planetesimals as stated by Kenyon and Bromley (2004a) or the stirring by planets orbiting the inner gap of the disc (Wyatt, 2005; Mustill and Wyatt, 2009). Another possible mechanism to ignite a cascade of collisions is e.g., perturbation by binary companion (e.g., Faramaz et al., 2014).

When the collisional cascade in a disc starts the solid material is broken to dust sizes and the smallest particles for which $\beta \gtrsim 0.5$, are expelled from the system by direct radiation pressure. In the dust size range (< 1 mm) stirring is not necessary, as typical eccentricities of the grains are of the same order as the β -ratio (Burns et al., 1979) and the impact velocities are sufficiently high due to radiation pressure.

In order to describe the collisions several parameters are necessary. An important one is the critical specific energy for disruption and dispersal, Q_D^* , which is defined as the impact energy per unit target mass. If the objects are small Q_D^* does only depend on the material strength, while for larger objects with sizes of ~ 100 m it is determined by the gravitational binding energy. Therefore, Q_D^* is often described as the sum of two power laws (e.g., Davis et al., 1985; Benz and Asphaug, 1999; Kenyon and Bromley, 2004b; Stewart and Leinhardt, 2009):

$$Q_D^* = Q_{\text{strength}} \left(\frac{s}{1 \text{ m}} \right)^{-b_{\text{strength}}} + Q_{\text{gravity}} \left(\frac{s}{1 \text{ km}} \right)^{b_{\text{gravity}}}. \quad (2.22)$$

The values for Q_{strength} and Q_{gravity} are of the order of $\sim 10^5 - 10^7$ erg/g, while b_{strength} lies between 0 and 0.5 and b_{gravity} between 1 and 2 (Benz and Asphaug, 1999). A minimum of $\sim 10^4 - 10^6$ erg/g of the critical energy is reached at sub-kilometre sizes, while at dust sizes Q_D^* should be of the order of $\sim 10^8$ erg/g. When the relative velocity of two colliders reaches or exceeds a critical value of

$$v_{\text{critical}} = \sqrt{\frac{2(m_{\text{target}} + m_{\text{projectile}})^2}{m_{\text{target}} m_{\text{projectile}}} Q_D^*}, \quad (2.23)$$

where m represents the masses of the colliders, the two colliders are disrupted (e.g., Krivov et al., 2005). Assuming particles of the same size, they will be destroyed if their velocity is larger than $\sqrt{8Q_D^*}$. Considering two dust grains, the critical velocity lies at several hundred metres per second. If they are situated at several tens of AU away from the star they would have an eccentricity of ~ 0.1 . As mentioned before, the eccentricity is in the same order as the β -ratio and thus particles with $\beta \sim 0.1$ could naturally attain such eccentricities.

However, the collisions in debris discs influence a size range of ~ 12 orders of magnitude and take place at different velocities. There are two important outcomes of collisions, namely the complete disruption and the cratering, which means partial destruction of one or both colliders with and without reaccumulation of fragments (Thébault and Augereau, 2007; Müller et al., 2010).

2.2.4 Grain sizes

In this work we use different terms for grain sizes, whereas most of them are connected to different methods of disc modelling:

1. Blowout grain size

In Section 2.2.2 it was mentioned, that if the β -parameter of a dust grain is $1/2$, the grain is of blowout size. Smaller grains which possess a larger value of β are expelled from the system by direct radiation pressure.

2. Dominant or typical grain size

This size is used for collisional modelling and corresponds to the largest cross section of dust in the

debris disc system.

3. Minimum grain size

This size represents the lower cutoff of a power law size distribution.

4. Characteristic grain size

Considering the MBB method, no dust grains are assumed during the SED fitting. Thus, the characteristic grain size proposed by Backman and Paresce (1993) is used. We assume the relation $\lambda_0 = s/(2\pi)$ in order to compare the characteristic grain size with the minimum grain size of the power law size distribution.

An illustration for them is given in Figure 2.9, where two different size distributions are depicted, one generated by collisional modelling and the other a power law distribution.

Figure 2.9: Cross section of dust as a function of grain radius. The red solid line represents a size distribution generated by collisional modelling, the blue solid line a power law size distribution. For more detailed explanations see text.

2.2.5 Flux density of a circumstellar debris disc

A debris disc is an optically thin disc (e.g., Zuckerman et al., 1995; Thi et al., 2001; Wolf and Hillenbrand, 2003). Hence, multiple scattering of radiation and heating of dust caused by dust reemission are negligible and the only radiation processes considered are absorption, reemission and scattering of stellar radiation by dust grains. The direct stellar radiation is the only source for the heating of dust particles.

Luminosities

The monochromatic luminosity of a star with the radius R_{star} and the effective temperature T_{star} at the wavelength λ is given by

$$L_{\lambda, \text{star}} = 4\pi R_{\text{star}}^2 \pi B_{\lambda}(T_{\text{star}}) \quad (2.24)$$

with $B_{\lambda}(T_{\text{star}})$ being the Planck function. Then a dust particle of size s , with a temperature T_{grain} at a distance r from the star absorbs

$$L_{\lambda, \text{grain}}^{\text{abs}} = L_{\lambda, \text{star}} Q_{\lambda}^{\text{abs}} \frac{\pi s^2}{4\pi r^2}, \quad (2.25)$$

and it reemits

$$L_{\lambda, \text{grain}}^{\text{em}} = 4\pi s^2 Q_{\lambda}^{\text{abs}} \pi B_{\lambda}(T_{\text{grain}}(r)). \quad (2.26)$$

Here Q_{λ}^{abs} is the absorption efficiency which is explained in Section 2.1. For the sake of energy conservation, the absorbed luminosity must be the same as the emitted one, meaning

$$\int_0^{\infty} L_{\lambda, \text{grain}}^{\text{em}} d\lambda = \int_0^{\infty} L_{\lambda, \text{grain}}^{\text{abs}} d\lambda. \quad (2.27)$$

If a particle's temperature $T_{\text{grain}}(r)$ is known, Equations (2.25) – (2.27) allow the derivation of the distance r of this particle from the star with

$$r(T_{\text{grain}}) = \frac{R_{\text{star}}}{2} \left[\frac{\int_0^{\infty} Q_{\lambda}^{\text{abs}}(s) B_{\lambda}(T_{\text{star}}) d\lambda}{\int_0^{\infty} Q_{\lambda}^{\text{abs}}(s) B_{\lambda}(T_{\text{grain}}(r)) d\lambda} \right]^{1/2}. \quad (2.28)$$

In case of blackbody grains, $Q_{\lambda}^{\text{abs}}(s)$ is equal to unity and not depending on the grain size s . The integral of $B_{\lambda}(T)$ is given by the Stefan-Boltzmann law $\int \pi B_{\lambda}(T) = \sigma T^4$, where σ is the Stefan-Boltzmann constant. Therefore, Equation (2.28) can be reduced to the blackbody radius

$$R_{\text{BB}}(T_{\text{grain}}) = \left(\frac{L_{\text{star}}}{16\pi\sigma} \right)^{1/2} \left(\frac{1}{T_{\text{grain}}} \right)^2. \quad (2.29)$$

The parameter L_{star} is the stellar luminosity. The blackbody radius R_{BB} is only a function of the particle's temperature and the stellar luminosity and is wavelength independent.

Flux densities

The luminosities given in Section 2.2.5 can be converted into flux densities, which are measurable parameters. An observer at a distance d from the star measures a flux density of

$$f_{\lambda}(r) = \frac{L_{\lambda, \text{grain}}^{\text{em}}}{4\pi d^2} = \pi B_{\lambda}(T_{\text{grain}}(r)) \left(\frac{s}{d} \right)^2 Q_{\lambda}^{\text{abs}} \quad (2.30)$$

for one single dust grain. Assuming an annulus with an area of $2\pi r dr$ and the resulting total number of dust particles $2\pi r N(r, s) ds$ in it, the flux density of the whole disc is given by

$$F_{\lambda}(r, s) dr ds = \frac{2\pi^2}{d^2} B_{\lambda}(T_{\text{grain}}(r)) Q_{\lambda}^{\text{abs}} N(r, s) r dr s^2 ds. \quad (2.31)$$

2.2.6 Fractional luminosity f_d

The fractional luminosity, f_d , is defined as the ratio of disc luminosity and stellar luminosity i.e.

$$f_d = \frac{L_{\text{disc}}}{L_{\text{star}}}, \quad (2.32)$$

whereas Equation (2.31), using the relation $L_{\text{disc}} = 4\pi d^2 \int \int F_{\lambda}(r, s) d\lambda ds dr$, changes it to

$$f_d = \frac{8\pi^3}{L_{\text{star}}} \int \int \int Q_{\lambda}^{\text{abs}}(s) B_{\lambda}(T_{\text{grain}}(r)) r s^2 N(r, s) d\lambda ds dr. \quad (2.33)$$

Using again the blackbody conditions, f_d is reduced to

$$f_d = \frac{8\pi^2\sigma}{L_{\text{star}}} \int_{R_{\text{min}}}^{R_{\text{max}}} \int_{s_{\text{min}}}^{s_{\text{max}}} (T_{\text{grain}}(r))^4 r s^2 N(r, s) ds dr. \quad (2.34)$$

With Equations (2.8) and (2.29) further transformation is possible. Assuming an infinitesimal ring width, the size distribution is only a function of the grain size: $N(s) \sim (s/s_0)^{-q}$. In that case, f_d is given by

$$f_d = \frac{4\pi\sigma}{L_{\text{star}}} T_{\text{grain}}^4(r) \int_{s_{\text{min}}}^{s_{\text{max}}} N(s) s^2 ds = \frac{A}{4\pi R_{\text{disc}}^2}. \quad (2.35)$$

Thus, the fractional luminosity represents the ratio of the dust's total cross section and the surface area of the sphere with the radius R_{disc} of the disc. In case of blackbody discs, the grain sizes are irrelevant and only the particle cross section is taken into account.

Minimum fractional luminosity

The fractional luminosity can be used as limiting case for observations, since there is a minimum necessary for a detection by a telescope. This minimum is calculated as follows. Using Equation (2.30), we assume the flux density of the dust to be

$$F_\nu = N_0 \times f_\nu, \quad (2.36)$$

where N_0 is the number of particles and f_ν the flux density measured for one particle at a certain frequency, ν . For this purpose no radial or size distribution of the grains, but a constant particle number is used. Furthermore, this particle number can be expressed by the dust mass, given by

$$M_{\text{dust}} = \frac{4\pi\varrho s_0^3 N_0}{3}, \quad (2.37)$$

with s_0 being the grain size of a spherical particle. Now, the telescope has a minimum flux density, F_ν^{min} , measureable at a certain frequency. Hence, there is a minimum dust mass at a certain disc radius necessary for a detection and due to the Planck law (see Equation (2.4)) the dust mass can be written as

$$M_{\text{dust}} = \frac{2\varrho\lambda^3 d^2 F_\nu^{\text{min}} s_0}{3hc} \left[\exp\left(\frac{hc}{\lambda kT}\right) - 1 \right]. \quad (2.38)$$

The fractional luminosity is calculated by Equation (2.32), where the luminosity of the disc is expressed by $L_{\text{disc}} = 4\pi d^2 F$, with F being the measured flux and d the distance from the observer. The flux is calculated by

$$F = \int_0^\infty F_\lambda d\lambda = \int_0^\infty \left(\frac{s_0}{d}\right)^2 \pi B_\lambda(T) N_0 d\lambda = \left(\frac{s_0}{d}\right)^2 \sigma T_{\text{BB}}^4 N_0. \quad (2.39)$$

Now, we use Equation (2.29) and express the minimum fractional luminosity with

$$f_d^{\text{min}} = \frac{4\pi d^2 F}{L_{\text{star}}} = \frac{\lambda^3 d^2 F_\nu^{\text{min}}}{8\pi hc \times r^2} \left[\exp\left(\frac{hc}{\lambda k} \left(\frac{16\pi\sigma}{L_{\text{star}}}\right)^{1/4} r^{1/2}\right) - 1 \right]. \quad (2.40)$$

Obviously, f_d^{min} is independent of the grain size and the density of the dust material and does only depend on the distance, the stellar luminosity and the disc radius. Since the detectable F_ν^{min} of the

telescope is different for each wavelength band, the wavelength is, besides the minimum flux density, an important parameter. In this work the *Herschel*/PACS instrument (Pilbratt et al., 2010; Poglitsch et al., 2010) is often used. It has a detectable minimum flux density of $F_{\nu}^{\min} = 5.5$ mJy in the 100 μm band¹. Assuming a Sun-like star at a distance of 10 pc from the observer and with a debris disc radius of 100 AU the minimum fractional luminosity necessary for detection of the disc is $f_d^{\min} \approx 8 \times 10^{-7}$. In comparison the Edgeworth-Kuiper belt of the Solar system has a fractional luminosity of $f_d = 1.2 \times 10^{-7}$ (Vitense et al., 2012). Therefore, analogues of this belt around other host stars would be undetectable with PACS.

Maximum fractional luminosity

In the last section we described the fractional luminosity being a limiting case for observations and called it the minimum fractional luminosity. Now, the collisional evolution of a debris disc gives another limiting case, that of a maximum fractional luminosity.

In a collisional cascade particles with a maximum diameter, D_c , are destroyed in collisions and replaced by smaller objects. Hence, the removal of objects with the highest mass in the collisional cascade determines the long-timescale evolution and as a consequence the total mass and the fractional luminosity decrease with the decreasing number of planetesimals of size D_c . Furthermore, the initial disc mass does not influence the disc mass of later times, since the mass of more massive discs is processed faster (Wyatt et al., 2007a). And so there is a maximum disc mass or maximum fractional luminosity, f_{\max} , respectively at a given disc age, t_{age} , which can be used as an upper limiting case. As given by Wyatt et al. (2007a) the maximum fractional luminosity can be described by

$$f_d^{\max} = 0.58 \times 10^{-9} \times r^{7/3} \times \frac{dr}{r} \times D_c^{0.5} \times Q_D^{5/6} \times e^{-5/3} \times M_{\text{star}}^{-5/6} \times L_{\text{star}}^{-0.5} \times \frac{1}{t_{\text{age}}}. \quad (2.41)$$

Using values given by Benz and Asphaug (1999), we assume for the critical energy $Q_D^* = 2000$ J/kg, for the planetesimal size $D_c = 2$ km and for the ring width $dr = 10$ AU. Furthermore, we use an eccentricity, e , of 0.1, which is comparable to that of the classical Edgeworth-Kuiper belt where $e \approx 0.08$ (e.g., Elliot et al., 2005; Vitense et al., 2010).

However, the model proposed by Wyatt et al. (2007a) contains two simplifications. At first, it is assumed that the debris disc is in collisional equilibrium for all sizes ranging from dust up to the largest planetesimals. The second assumption is related to the minimum specific energy necessary to disrupt the colliding objects. In reality this energy depends on the sizes of the colliders, but here, it is independent of them. An improvement of the model was done by Löhne et al. (2008) who lifted these simplifications, but as a consequence, the maximum fractional luminosity is still determined by the initial disc mass here. Therefore, we decided to use the easier model proposed by Wyatt et al. (2007a). It is possible that the fractional luminosity of an observed debris disc is higher than the predicted maximum fractional luminosity (e.g., Wyatt et al., 2007b) caused by simplifications used. In such cases an adaption of the parameter values (Q_D^* , e , t_{age} or D_c) is possible or the usage of the improved model proposed by Löhne et al. (2008). However, if the measured f_d is much higher than f_d^{\max} it is assumed that the disc did not produce dust from the beginning, but started the production at a later time. In Figure 2.10 both the minimum and maximum fractional luminosity are depicted considering a debris disc around a solar-type star.

Figure 2.10: Fractional luminosity as function of disc radius. Red solid line: maximum fractional luminosity for a debris disc around a solar-type star with an age of 100Myr. Blue solid line: minimum fractional luminosity for a debris disc around a solar-type star at a distance of 35pc at 100 μ m using *Herschel*/PACS. Red squared and blue lined areas show regions where no debris disc is detectable with the parameters (distance, age, ...) used.

2.3 Statistical basics

2.3.1 Correlation coefficients

This work is concentrating on statistical analysis of debris discs and as such is looking for correlations between circumstellar system parameters, e.g., stellar luminosity and disc radius. In order to prove the statistical significance of these correlations, we will use the correlation coefficients of Pearson and Spearman.

The Pearson coefficient requires a linear correlation between the two parameters compared and is given by

$$r_{\text{Pearson}} = \frac{\sum_{i=1}^{N_{\text{data}}} (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{N_{\text{data}}} (x_i - \bar{x})^2 \sum_{i=1}^{N_{\text{data}}} (y_i - \bar{y})^2}}, \quad (2.42)$$

where x_i and y_i are the values of the data points of both parameters, \bar{x} and \bar{y} the arithmetic mean values of the data points and N_{data} the number of data points (e.g., Hedderich and Sachs, 1968). The coefficient is normalised and can vary between -1 and 1. To check whether the calculated value represents a significant correlation it is necessary to calculate the t -value of the Student's t -distribution and to choose a significance level, which we will set to 1%. The t -value is given by

$$t = r_{\text{Pearson}} \cdot \sqrt{\frac{N_{\text{data}} - 2}{1 - r_{\text{Pearson}}^2}}. \quad (2.43)$$

Using the significance level chosen before, there is a critical value of t , namely t_{critical} , depending on the number of data points. It is listed in the literature, e.g. Hedderich and Sachs (1968) and Bronstein et al. (1977). The correlation is significant, if t is larger than this critical value. In terms of r_{Pearson}

this means the correlation is significant for

$$|r_{\text{critical}}| > \frac{t_{\text{critical}}}{\sqrt{t_{\text{critical}}^2 + N_{\text{data}} - 2}}. \quad (2.44)$$

The Pearson correlation coefficient has the disadvantage of requiring a linear correlation between the parameters compared. Furthermore, it is highly influenced by possible outliers of the data sets, which could lead to wrong conclusions. Therefore, we will use the Spearman rank correlation coefficient as well, since this coefficient does not require linearity and is not influenced by outliers. Here, both parameter data sets are transformed into rows of rank numbers, e.g., the lowest value gets rank number 1 and the highest rank number N_{data} . Afterwards, the difference, D , of the two rank numbers is calculated and the correlation coefficient is given by Hedderich and Sachs (1968) as

$$r_{\text{Spearman}} = 1 - \frac{6 \sum_{i=1}^{N_{\text{data}}} D^2}{N_{\text{data}}(N_{\text{data}}^2 - 1)}. \quad (2.45)$$

2.3.2 k-sample tests

Another part of the statistical analysis are k-sample tests which shall prove whether two subsamples stem from the same population or not. The selection criteria for one or another subsample are chosen from the system parameters. For example the targets can be sorted by their fractional luminosity, which results in a subsample with low and in one with high fractional luminosity objects. Then it is tested whether the two subsamples follow the same correlations between different system parameters. There are many different testing methods for this case, e.g. the Student's t-test, the Kolmogorov-Smirnov test and the Anderson-Darling test. If the sorting parameter values were distributed normally, the Student's t-test would be the easiest way of checking. However, we do not expect these parameters to be distributed normally and so this test is not an appropriate solution. On the other hand the Kolmogorov-Smirnov test (e.g., Kolmogorov, 1933; Smirnov, 1939, 1948; Massey, 1951) is independent of a specific distribution or the sample size, so it seems to be the most sensitive test for the problem mentioned in this work. Nevertheless, this test holds some disadvantages. It is only appropriate if the empirical distribution functions (EDFs) of the samples do not cross each other and if their difference is large near the centre of the distribution. If the EDFs have their largest difference at the beginning or the end of the distribution this test is insensitive (Hedderich and Sachs, 1968). In order to overcome these two disadvantages the Anderson-Darling test (AD test) was developed (e.g., Anderson and Darling, 1952, 1954; Darling, 1957; Scholz and Stephens, 1987; Feigelson and Babu, 2012) and was applied to the case of this work. The AD test provides the testing value A^2 , which is given for two samples by

$$A^2 = \frac{1}{n_1 + n_2} \sum_{i=1}^k \frac{1}{n_i} \sum_{j=1}^{n_1+n_2-1} \frac{((n_1 + n_2)M_{ij} - jn_i)^2}{j(n_1 + n_2 - j)}. \quad (2.46)$$

Here, n_i is the size of the i -th sample, $k = 2$ the number of samples and M_{ij} the number of data points in the i -th sample smaller than the data point Z_j of the pooled ordered sample ($Z_1 < \dots < Z_{n_1+n_2}$). The A^2 parameter is standardised to

$$T \equiv \frac{A^2 - (k - 1)}{\sigma}, \quad (2.47)$$

where σ is the standard deviation of A^2 . The null hypothesis is rejected at a significance level α if $T \geq t_{k-1}(\alpha)$. For $k = 2$ and a significance level of $\alpha = 0.05$, the critical percentile value is $t_1 = 1.960$, while it is $t_1 = 3.752$ for $\alpha = 0.01$ (Scholz and Stephens, 1987).

3 Technical aspects of fitting spectral energy distributions

After introducing the basic terms of a debris disc system and the methods of describing a SED we now come to the question of how we can model such a SED and thus we will explain the technical execution of SED fitting.

3.1 Fitting algorithm

3.1.1 Functionality

The SEDUCE code (Müller et al., 2010) was first designed to calculate SEDs of optically-thin circumstellar discs. With given input parameters, such as minimum grain size s_{\min} or disc radius R_{disc} , the SED can be derived directly with this code. Therefore, information on these parameters have to be taken from the literature or catalogues, but in most of the cases the values are unknown. Furthermore, the shape of the SED is known in general since the flux densities at certain wavelengths can be measured, but the parameters leading to the measured flux densities are not. So the real problem is of indirect nature, actually – which parameter values lead to the observed photometric data points of the SED? To solve this problem a fitting tool is necessary. This tool should minimise the deviation of the model-SED from the observed data points. A common parameter to express the quality of the fit is the χ^2 -parameter. It is given as

$$\chi^2 = \sum_{i=1}^{N_{\text{data}}} \left(\frac{F_i^{\text{observed}} - F_i^{\text{model}}}{\sigma_i^{\text{observed}}} \right)^2, \quad (3.1)$$

where in case of this work N_{data} is the number of photometric data points, F_i the observed and modelled flux densities and σ_i the uncertainties of the observed flux densities. Since the value of this parameter is larger for a larger number of data points it has to be normalised in order to compare fitting results of different objects. Hence, the reduced χ^2 is used, which is given as

$$\chi_{\text{red}}^2 = \frac{\chi^2}{N_{\text{data}} - N_{\text{parameter}} - 1}. \quad (3.2)$$

Here, the value of this parameter is less or equal to unity for a good fit and thus, the problem of fitting is to minimise χ^2 .

There are several methods of finding global minima, for example rasterising the parameter space, the Downhill simplex or the Powell method (Press et al., 2002), which all have their advantages and disadvantages. we chose the “simulated annealing” method, since it is an easy algorithm to implement and in addition, it does not require knowledge of the shape of the χ^2 -function. The simulated annealing makes use of the analogy with the thermodynamical freezing processes of liquids. The molecules of a liquid move freely at high temperatures, but they loose their ability of moving during the cooling process. If this cooling process is slow, the molecules are able to form a crystal and get to the minimum

energy state of the system. If the process passes fast, the minimum energy state cannot be reached. The molecules form an amorphous or a polycrystalline system, which has a higher energy. Analogue to that the global minimum is found by a slow approach. Figure 3.1 shall illustrate this. The diagram

Figure 3.1: Objective function for the simulated annealing. Blue filled circle: starting point for fitting iteration; green filled points: iteration progress points; red filled circle: global minimum and goal of fitting process. See text for further details.

shows a function with two minima. While the minimum on the left side is just local, the minimum on the right is both a local and a global one and so the one we are looking for. In order to get the minimum we have to start at an arbitrary point (“Start”). It is given by a set of default parameter values. Then a new set of parameter values is chosen at random and therefore, a maximum step size $step_{\max}$ is defined for each parameter. The randomly chosen step sizes lie between $[-step_{\max}, +step_{\max}]$ and thus, the new parameter values increase or decrease by this summand. This leads to a new function value χ^2 . For instance this point could be one of the circles numbered with 1, 2 or 3. Now, the function value of the starting point and the new value are compared. In case of circle 1 the parameter χ^2 is lower than the starting value and so we are approaching a minimum. The set of parameters which led to this point is taken as the temporary parameter set of the minimum. For circle 2 the χ^2 value is larger and therefore we took the wrong direction in parameter space. Here, the parameter values of the starting point stay as the temporary parameter set of the minimum.

The value of χ^2 may be larger, but there is a possibility for a further minimum. Circle 3 illustrates this. On the left side of it the χ^2 -values decrease and lead to a minimum. On its right side the values increase, but as it is shown another minimum (the goal) can be reached. This is the problem, where the simulated annealing method takes place. The probability of not reaching a minimum after increasing values of χ^2 is not constant. It follows the slow annealing process with the shape of

$$P(\chi^2) \sim \exp\left(-\frac{\chi^2 - \chi_{\text{start}}^2}{T}\right), \quad (3.3)$$

where χ_{start}^2 is the value of χ^2 of the starting set of parameter values and T the so called annealing function. The acceptance threshold $P(\chi^2)$ is picked from $[0, 1]$ by a random generator and then compared to the value of the right side of Equation (3.3). In case of $P(\chi^2)$ being larger than the right side, the parameter values are reset to the values of the starting point and the annealing function T decreases. This means, the finding of another minimum in this direction of parameter space is

unlikely. The other case is $P(\chi^2)$ being smaller than the right side of Equation (3.3). Here, the values are accepted as the new starting point for the next χ^2 -calculation and the annealing function does not change. When the annealing function finally reaches a fixed minimum, since there are no better χ^2 -values reachable, the set of parameter values found for the temporary minimum of χ^2 is taken as the global minimum parameter set.

3.1.2 Advantages and disadvantages

As we mentioned before, each algorithm holds several advantages and disadvantages and so does the simulated annealing. As an iterative improvement algorithm the simulated annealing finds always a local minimum during the fitting process, but whether this minimum is the global one or not cannot be said since there is no information on that. Furthermore, the result of the fitting process depends on the input parameter values and therefore the starting point. In general there are no constraints for them, but in this work physical expectations can be used as a first guess. For instance, the minimum grain size should lie at several microns and thus a starting value of one metre would not be appropriate. And last but not least the computation time of the whole process cannot be estimated in general and in the worst case the fitting can be an open problem (Laarhoven and Aarts, 1987).

On the other hand, the simulated annealing can be applied to general problems without knowledge of the function to minimise, which is the case for the χ^2 -function of this work. In addition it is an easy algorithm to implement and the computation time for one iteration is small. There are also possibilities to avoid some of the disadvantages mentioned above, for example the usage of a sample of starting points.

All in all, despite some disadvantages this algorithm is a good choice for the χ^2 -minimisation, since it can easily be adapted to special problems and therefore offers a high degree of flexibility necessary in this work.

3.2 Fitting procedure

3.2.1 Criteria for one- and two-component systems

Images reveal that debris discs may possess several rings comparable to the Asteroid and the Edgeworth-Kuiper belt in our Solar system (e.g., Roberge et al., 2013; Donaldson et al., 2013; Su et al., 2015; Matthews et al., 2015). Hence, SEDs of debris disc systems may contain several components as well. Figure 3.2 shows, that in the visual and near infrared range the stellar radiation dominates, whereas in the mid-infrared the radiation of the debris disc dust gains more influence on the measured flux densities. Finally, the far-infrared is dominated by the disc’s radiation and the star is nearly negligible. Thus the SED can contain a warm component (an “Asteroid belt”) for instance, which has more influence in the mid-infrared, and a cold one (an “Edgeworth-Kuiper belt”), which dominates the far-infrared region (see Figure 3.2 left panel). So, in order to fit a SED properly, it has to be proved whether a warm dust component is present in the system or not. Unfortunately, the majority of the observed images cannot reveal or resolve a warm component. Hence, we have to use selection criteria given by the SED itself.

At first, we start to fit the far-infrared photometric points beginning at a wavelength of 70 μm . Here, the near-infrared and mid-infrared photometry is not included in the fitting process, since we want to test, whether the data can be fit well with just one component or not. An exemplary result for such a fit is given in Figure 3.2 in the left panel. There is a clear deviation of the mid-infrared photometry from the model data, which indicates the existence of a second, warmer component shown

Figure 3.2: Left panel: Typical SED of a debris disc system fitted with one dust ring (cold component shown in blue). Green filled circles show observational points with error bars. Deviation of model values and observational points in the MIR region indicate the existence of a second dust ring (warm component). Right panel: Typical SED of a debris disc system fitted with two dust rings (cold component shown in blue, warm component shown in red.)

in the right panel. In order to prove this assumption the mid-infrared model flux densities of the best fit are compared to the mid-infrared photometric points measured for each disc. Here, the measuring instruments are the InfraRed Spectrograph (IRS)¹ and the Multiband Imaging Photometer (MIPS)² of the *Spitzer* Space Telescope as well as the Wide-Field Infrared Survey Explorer (WISE, Wright et al. (2010)) (see Section 4.3.1 for details). We use the parameter $\sigma \equiv (F_i^{\text{observed}} - F_i^{\text{model}}) / \sigma_i^{\text{observed}}$ to quantify the significance of an excess. If there is a significant excess at the mid-infrared bands of *Spitzer* IRS/22, WISE/22, *Spitzer* MIPS/24 and *Spitzer* IRS/31, meaning the measured flux densities deviate more than 3σ from the derived model flux densities, then an excess is assumed. Otherwise the second component is refused and the system is fitted with one dust component.

Now, it has to be checked, whether the fit with a second component has a significant better quality than the fit with one component. Therefore, the χ^2 of the one-component fit (shown in the left panel of Figure 3.2) is calculated including the mid-infrared data points starting at $10 \mu\text{m}$. At this wavelength the measured flux densities of our sample start to deviate from the pure photospheric spectrum of the host star. The resulting χ^2 -value is compared to the χ^2 -value of the two-component fit, which has included the mid-infrared points as well. If the quality of the two-component fit is three times better than that of the one-component fit, meaning if $\chi_{\text{one}}^2 / \chi_{\text{two}}^2 > 3$, then the second component is confirmed. The same criterion was used by Ballering et al. (2013)

The third criterion includes the physical parameters of the warm component. Since the dust is fit with a certain material, such as astronomical silicate or carbon, a sublimation temperature exists, for which the material changes from a solid to a gaseous state. If the warm component would be set too close to the star, the ring temperature would reach the sublimation temperature of the material. In this case the dust particles would disappear and no thermal emission could be measured. The fitting tool uses the disc radius as input parameter and calculates then the temperature of the grains. Hence, the radius of the ring must be larger than the sublimation radius, for which the sublimation temperature is reached.

Finally, if all three of the before mentioned criteria are fulfilled, a second dust component is assumed

¹IRS Instrument Handbook, Version 5.0;
<http://irsa.ipac.caltech.edu/data/SPITZER/docs/irs/irsinstrumenthandbook/home/>

²MIPS Instrument Handbook, Version 3;
<http://irsa.ipac.caltech.edu/data/SPITZER/docs/mips/mipsinstrumenthandbook/home/>

for the debris disc system. In all other cases it is refused and the system is assumed to have just one ring component.

3.2.2 Fitting of one-component systems

A debris disc system is fit with one dust component, if at least one of the above mentioned criteria is missed. In this case all photometric points starting at a wavelength of $10\ \mu\text{m}$ are included in the fitting process. As explained before, the SED fitting of debris discs can be done by using different methods, e.g., the blackbody (BB), the modified blackbody (MBB) or the size distribution (SD) method. Each has its advantages and disadvantages and hence it is not possible to say generally that one method is better than the other one. For statistical analysis of large samples with hundreds of discs it is necessary that the fitting process is fast and that all discs can be modelled without much effort. Therefore, the blackbody method is often chosen (e.g., Ballering et al., 2013; Chen et al., 2014; Kennedy and Wyatt, 2014), since for this method only the amount of dust material and the dust temperature of the disc have to be fit. Obviously, the simplicity of this kind of modelling does not allow conclusions about the properties of the dust grains, such as particle size or composition, but predictions about dust temperatures or the existence of a second component dust ring are possible. The purpose of this work is to statistically investigate the dust properties of debris discs. Therefore, the BB-method is not appropriate for this problem and other methods have to be applied. As could be seen in Chapter 2.1, we will concentrate on the MBB and SD method.

MBB method

The MBB method makes use of the simplicity of the blackbody fitting, but here, conclusions about dust grain sizes can be made as well. Since the number of modelling parameters is increased to three (amount of dust material, cut-off wavelength and opacity index) compared to the BB method, the process is not as fast as for the BB fitting, but statistical analysis of moderately large samples can be easily done (e.g., Moór et al., 2006; Booth et al., 2013; Donaldson et al., 2013; Pawellek et al., 2014; Moór et al., 2015). An example for a SED using the MBB method is given in Figure 3.3. The artificial

Figure 3.3: SED generated with the MBB method.

“knee” generated by the cut-off wavelength λ_0 can be seen easily. Furthermore, the influence of β_{mod} in the far-infrared region is shown. The larger β_{mod} is, the steeper is the decrease.

SD method

The SD method follows another idea. Here, a more realistic modelling of the dust material is foregrounded at the expense of the fitting fastness. The modelling parameters are now the amount of dust material, the size distribution parameters (e.g., minimum and maximum grain size, size distribution index), the radial parameters (e.g., minimum and maximum radius of the disc, radial distribution index) and the dust composition parameters (e.g., absorption efficiency, density). A statistical analysis of a large or even a moderately large sample of discs with this method is very time expensive and therefore impossible, if there are no fixed parameters or parameter constraints. In Figure 3.4 an example for a

Figure 3.4: SED generated with the SD method for fixed radial parameters. Only the grain size parameters are varied.

SED generated with the SD method is given. While the minimum grain size of the size distribution has its largest influence in the mid-infrared region ($\sim 30 - 50 \mu\text{m}$), the size distribution index, q shows a similar behaviour than the β_{mod} of the MBB method. The larger q is, the steeper the decrease at far-infrared wavelengths.

The first part in the fitting process for both methods is to calculate the dust optical properties (e.g., Q_{abs}) of each grain size and then determine the absorbing and emitting luminosity (see Equations (2.25) and (2.26)). Assuming energy conservation (Equation (2.27)) the distance of the dust particle to the star can be determined (Equation (2.28)) through numerical integration. At each fitting step (see Section 3.2) the fitting parameter values are randomly selected within the valid range, while the resulting model flux densities are calculated including a normalisation to the measured photometric points in height, which represents an adaption of the dust mass (see Equation (2.12)). This means, that there are at least three free parameters and therefore, five photometric data points are necessary in order to fit the SED properly (see Equation (3.2)). Otherwise, the fitting process cannot uniquely constrain the system parameters given the complexity of the model.

3.2.3 Fitting of two-component systems

The fitting procedure of a two-component debris disc system is similar to the fit of the one-component system. Here, the first step is to fit the SED only with the cold component just including the far-infrared points ($\lambda \gtrsim 70 \mu\text{m}$). Then, the best fit parameters of the cold component are fixed and

the warm component is added and fit assuming a pure blackbody model, now including the mid-infrared points ($\lambda \gtrsim 10 \mu\text{m}$) as well. After that, the warm component parameters are fixed and the cold component is adapted again. This iteration process is repeated until no further improvement of the SED model is possible, i.e. the χ^2 cannot be reduced anymore. In order to fit a two-component system, at least seven photometric data points are necessary since five free parameters do exist.

3.3 Degeneracy of fit parameters

The fitting of a SED bears the problem that the radial parameters are degenerated with the grain size parameters. This means, that a SED can be fit either with large grains at a small distance to the star or with small grains at a larger distance. The reason for this effect is given in Figure 2.7 for instance. The dust grains of different sizes have different temperatures at the same stellocentric distance. In general, large grains are colder at a certain distance than small ones. Furthermore, the dust composition plays a role in the degeneracy as well, which can be seen in Figure 2.6 in the right panel. Dust grains of the same size but made of different materials have different temperatures, too.

Figure 3.5: SED of a debris disc for different disc radii, grain sizes and dust materials.

Figure 3.5 does explain this in more detail. The same SED can be reproduced by using different parameters. For astronomical silicate we can either use a disc of 10AU and a minimum grain size of $20 \mu\text{m}$ or a larger radius of 30AU and a small grain size of $1 \mu\text{m}$. If we change the dust composition to carbon and set the radius to 30AU as well the minimum grain size changes to $2 \mu\text{m}$.

As a consequence, it is necessary to find constraints on the radial parameters or the grain size parameters in order to get reliable results from the SED fit. Using resolved debris discs, which is the basic idea of this work, and assuming a narrow annulus for each disc component, the radial parameters can be fixed and the degeneracy between disc radius and dust grain size can be broken.

3.4 Determination of error bars

After fitting the SED, it is useful to know, how reliable the results are. Therefore, it is necessary to calculate the uncertainties of the fit parameters. The method used was suggested by Steve Ertel (Steward Observatory, University of Arizona; Ertel (2012)) and is done the following way. Considering the parameter space, the initial point of the calculation of the fit uncertainties is the point of the

best fit parameter values. From here, a new annealing process is started, with the difference that Equation (3.3) is changed to

$$P(\chi^2) \sim \exp(\chi_{\text{start}}^2 - \chi^2), \quad (3.4)$$

and no annealing temperature is assumed in order to avoid weighting effects. In the next step it is counted how often a certain parameter value is reached. Therefore, all values are grouped into equal-sized bins. The resulting distribution in the parameter space represents an estimate of the probability distribution of the parameters and is the basis for the calculation of the confidence interval of the parameters. Such a probability distribution is given in Figure 3.6. It is obvious that the most counts

Figure 3.6: Probability distribution in the parameter space of minimum grain size and size distribution index in arbitrary units. The colour range gives the absolute frequencies of the pairs of parameter values.

are situated between 3 and 3.5 of the minimum grain size and between 3.55 and 3.57 of the size distribution index. Assuming a normal distribution here, the standard deviation for a fit parameter can be calculated by

$$s_{\text{parameter}} = \sqrt{\frac{1}{N} \sum_{i=1}^N (x_i - \bar{x})^2}, \quad (3.5)$$

where N is the total number of the counted parameter values, x_i the values themselves and \bar{x} the mean value of the parameter. In the following parts of this work the standard deviation is taken as the uncertainty of the fit parameter, thus we use the 1σ confidence interval.

One important point is the width of the parameter grid in the fitting process. If the width of the grid nodes is too broad, the uncertainty is overestimated and increases with increasing grid width. So the grid must be fine enough in order to avoid that effect. On the other hand, if the width of the grid nodes is too narrow no normal distribution can be reached in an adequate time. Figure 3.7 shows the resulting probability distribution for different grid widths. In the left panel the grid has a very small width and thus no normal distribution is visible. In the right panel the grid width is chosen very large and the normal distribution is broadened. Hence, the uncertainties are overestimated here. The panel in the middle represents the best choice for the grid width.

Figure 3.7: Probability distribution in the parameter space of minimum grain size and size distribution index in arbitrary units. The colour range gives the absolute frequencies of the pairs of parameter values. The grid width varies from $\Delta s = 0.01$ and $\Delta q = 0.001$ (left) over $\Delta s = 0.1$ and $\Delta q = 0.01$ (middle) and $\Delta s = 1.0$ and $\Delta q = 0.1$ (right) with Δs being the width of the grain size grid and Δq the grid of the size distribution index.

4 Sample

In the previous chapters we gave an introduction to the description of debris discs and explained the technical way of modelling a SED. Since the theory is known now, it is time to choose the appropriate targets for the SED fitting.

4.1 Resolved debris discs

In Chapter 3.3, we described the problem of degeneracy between the radial, grain size and dust composition parameters of debris discs. In order to model a SED it is necessary to break these degeneracies and one possibility is given by resolved debris discs. Here, the disc radii are known and so the grain sizes can be calculated for given dust compositions. Over the last years many debris discs were found around a wide range of spectral types and could be resolved in one or more wavelength bands with different instruments. At this time nearly one hundred spatially resolved discs are known around stars with spectral types ranging from B to M (see Table C.1). Thus we have the opportunity to select the most appropriate discs.

4.1.1 Selection criteria

In this work we are going to derive statistical correlations between disc parameters and stellar properties. Therefore, it is necessary that the selected discs fulfill several requirements in order to minimise the uncertainties in the statistical results.

Figure 4.1: Stellar systems revealing peculiarities. Left panel: 61 Vir (Wyatt et al., 2012), middle panel: β Pic (Lagage and Pantin, 1994), right panel: ϵ Eri (Greaves et al., 2014b).

Every instrument observing discs has its own properties and data reduction system. To avoid possible biases caused by different instruments, we chose discs which were all resolved with *Herschel* Photoconductor Array Camera and Spectrometre (PACS) (Pilbratt et al., 2010; Poglitsch et al., 2010). Furthermore, the selection of photometric data points which are the basis of SED fitting is important. Reliable fitting results are only possible with a reliable set of data points including a wide wavelength range. As a result each disc chosen for this work must have at least two high signal-to-noise flux densities in the PACS bands (70 μ m, 100 μ m, 160 μ m).

Considering the statistical purpose of our thesis the homogeneity of the sample is important as well. Hence, we excluded discs revealing peculiarities such as substantial asymmetries in the resolved image (e.g. β Pic; Golimowski et al. (2006)) or nearby galaxies contaminating the disc image (e.g. 61 Vir; Wyatt et al. (2012)). We excluded discs with central peaks (e.g. ϵ Eri; Backman et al. (2009)) as well, since the determination of the disc radius identified with the location of the maximum surface brightness (see Chapter 5) would lead to wrong values in such cases. In Figure 4.1 examples for such peculiar discs are depicted.

4.1.2 Resulting sample

Using the criteria mentioned above, there are 39 objects out of ~ 100 chosen for this work and Table 4.1 lists the resulting selection. The objects are distributed over a broad range of spectral types (M to B). Figure 4.2 shows the frequency of objects as a function of spectral type and stellar age. Most of the

Figure 4.2: Left: Frequency of resolved debris discs as function of spectral type. Black bars represent the selected sample of 39 resolved objects and gray bars the whole number of 100 objects. Right: Frequency of resolved discs of the 39-disc-sample as function of stellar age. For each star with more than one age reference, the age given is the geometric mean value reported in those papers (see Table (4.2)).

host stars of the discs chosen have spectral type A (20 targets) or F (7 objects). There are 7 K-type stars, two G and two M-stars and one B-type star. Besides targets of luminosity class V the sample contains class III and IV stars as well. The stellar ages vary between 15 Myr and 2500 Myr and show an equal distribution over the range. The sample does not claim completeness and could be biased in several ways. In order to check it for possible biases we made additional tests which are explained in Chapter 5.

4.2 Stellar parameters

Knowing the influence of the host star(s) of a debris disc is necessary in order to compute the excess emission and to fit a SED properly. Therefore, it is essential to derive the photosphere from the stellar parameters. In this work these parameters were collected from the literature. If different values were given for one target, the arithmetic mean value was taken, except for the stellar ages where the geometric mean was used. In Table 4.2 the resulting values are listed.

Stellar photospheres

The stellar photospheres were modelled by Benjamin Montesinos (Departamento de Astrofísica, CAB, CSIC-INTA) in the following way. With the stellar parameters the synthetic spectra were calculated by interpolating the PHOENIX/GAIA model grid (Brott and Hauschildt, 2005). The two stars HD 182681 and HD 188228 have stellar temperatures above 10000K. Since the PHOENIX grid does not go beyond this temperature, these models were replaced by ATLAS9 models (Castelli and Kurucz, 2004).

The SEDs were built using the optical and near-infrared data from different catalogues. The Hipparcos catalogue (CDS catalogue I/239/hip_main) provided the Johnson BV and the Cousins I_c

photometry, and Cutri et al. (2003) (CDS catalogue II/246) the 2MASS JHK_s photometry. The photometric points were given in magnitudes, so a transformation to flux densities was necessary. Therefore, the calibrations by Bessell (1979) (BVI_c) and Cohen et al. (2003) (JHK_s) were used. Then the generated model photospheres for each star were normalised to the given photometry by taking the I_c flux density as reference. The 2MASS data were not used for normalisation since for a number of targets these data were of poor quality. The object GJ 581 was an exception since here, the 2MASS K_s data were used. This was done in order to reach a better fit to the photometry points in the near-infrared.

Correction for extinction

Another aspect is the possibility that distant objects are affected by extinction. If that is the case, the stellar photospheres have to be corrected in order to get a realistic result for the stellar influence. All of the targets of the sample are located in the Local Bubble ($d < 100\text{pc}$), where the extinction in the optical band is $A_v \lesssim 0.1\text{mag}$ (e.g., Frisch et al., 2011; Reis et al., 2011). The uncertainties in the measured magnitudes are of the same order. We assume $A_v = 0.2\text{mag}$ as the worst case, as well as an extinction ratio $A(I_c)/A_v \approx 0.5$ referring to the I_c band to which the stellar photospheres were normalised (Rieke and Lebofsky, 1985). Hence, the extinction for the objects should be of the order of $\lesssim 0.1\text{mag}$. Without dereddening the true photospheric flux density would be underestimated by $\lesssim 10\%$ in that case. Considering the mid-infrared, where the excess flux densities lie only slightly above the photospheric ones, there would be an overestimate of the excess by the same 10%, which is the highest possible uncertainty only reachable for the largest extinction and excess flux densities close to the photospheric ones. Referring to the sample chosen for this work the uncertainty due to extinction lies at several percent and is comparable to the measurement uncertainties in the mid-infrared.

Nine stars which were all observed by the OT1_pabraham_2 programme were checked for possible extinction, including the most distant objects of the sample, HD 21997 ($d = 71.9\text{pc}$) and HD 95086 ($d = 90.4\text{pc}$). Only HD 21997 revealed reddening, where A_v was found to be $\approx 0.16\text{mag}$, and hence $A(I_c) = 0.08\text{mag}$. The flux density at $24\mu\text{m}$ is 2.2 times the photospheric flux density and therefore, the estimated uncertainty due to reddening is 4%. Looking at the far-infrared region the excess flux densities are one to three orders of magnitude higher than the photospheric ones and hence the extinction effect is negligible here.

4.3 Photometry

4.3.1 Mid-infrared photometry

We used flux densities at wavelengths longwards of $10\mu\text{m}$ in the SED modelling, including *WISE*/12 and /22 (*WISE* All-Sky Release Catalog; Wright et al. (2010)), *AKARI*/18 (*AKARI* All-Sky Catalogue; Ishihara et al. (2010)), measurements taken with MIPS/24 (e.g., Su et al., 2006; Chen et al., 2012) and IRS of the *Spitzer* Space Telescope. (e.g., *Spitzer* Heritage Archive; Chen et al. (2014) and CASIS archive¹, Lebouteiller et al. (2011); Werner et al. (2004)). In some cases Gemini/MICHELLE data were provided (Churcher et al., 2011a) as well as MMT/BLINC (Stock et al., 2010) and Keck/MIRLIN (Wahhaj et al., 2007). We took the photometric data from the literature, if they were given. In cases where no values were reported there, we took them from the above mentioned catalogues, which we accessed through Vizier and NASA/IPAC Infrared Science Archive. All photometric data can be found in Table A.1.

Notes:

The effective temperatures, metallicities and gravities are averaged over the listed literature values. ^aGray-Corbally notation. See App. A2 in Trilling et al. (2007) for its explanation. The stellar masses were taken from the literature or computed from the luminosities by means of a standard relation $M \propto L^{1/3.8}$ if no mass value was given. Exceptions for other luminosity classes or close binaries are the following: ^bstellar mass from Moór et al. (2013a) (giant); ^c stellar mass from Bonsor et al. (2012) (subgiant); ^dsum of the stellar masses from Kennedy et al. (2012a) (close binaries); ^estellar mass from Booth et al. (2013) (subgiant); ^fFor each star with more than one age reference, the age given is the geometric mean of the values reported in those papers.

4.3.2 Far-infrared and sub-mm photometry

For the majority of targets in the sample the *Herschel*/PACS and SPIRE² (Griffin et al., 2010) fluxes were derived in the original papers, cited in Table 4.1. In contrast to Pawellek et al. (2014) this work includes five additional K-stars, whose data were not all published yet. Furthermore, there are different

²Spectral and Photometric Imaging Receiver

reduction methods employed by different groups and so the photometric data had to be derived for the first time or cross-checked. This was done by Jonathan Marshall (University of New South Wales) the following way. The data were reduced by using the *Herschel* Interactive Processing Environment (HIPE, Ott, 2010), user release 10.0.0 and PACS calibration version 45. From the Herschel Science Archive (HSA) the level 1 data, which means basic calibrated data, were obtained and processed by using the standard pipeline script with a pixel fraction of 1.0, a pixel size of $1''$ at 70 and $100\ \mu\text{m}$ and $2''$ at $160\ \mu\text{m}$, respectively. Furthermore, it was adopted that the high pass filters had a width of 15, 20 and 25 frames. In order to avoid the skewing of the background measurement, a region with a radius of $20''$, which was centered on the expected star location, and other sources with a $\text{SNR} \geq 5$ (as measured by sextractor in the observation's level 2 scan from the HSA), were masked from the high pass filtering process. The performance of the deglitching was done by the second level deglitching task which is appropriate for bright sources. If a target was observed with the two channel combinations of 70/160 and 100/160 the final mosaic was produced by the combination of the four $160\ \mu\text{m}$ scans.

The usage of an IDL script based on the APER photometry routine from the IDL astronomy library³ allowed the measuring of the flux densities. The radius of the flux aperture varied in the PACS images. This depended on the extent of the disc, which lied typically between $15''$ – $20''$. The apertures were corrected in the way provided by Table 2 of Balog et al. (2013). For $15''$ aperture radius these are 0.829 at $70\ \mu\text{m}$, 0.818 at $100\ \mu\text{m}$, and 0.729 at $160\ \mu\text{m}$. For $20''$ aperture radius the correction factors are 0.863, 0.847 and 0.800, respectively. The sky background and the r.m.s. variation had to be estimated as well. This was done by the calculation of the mean and standard deviation of five square apertures with sizes which matched the same area as the apertures of the flux densities at each wavelength and for each target. At distances of $30''$ – $60''$ from the source peak the sky apertures were now randomly scattered, whereas for Vega (HD 172167) and HR 8799 (HD 218396) these distances were larger since they have very extended discs. This was done in order to avoid the central region where the target disc lay and in order to avoid any identified background sources in the image. The apertures of $35''$ for sky boxes are many times bigger than a single native pixel of $3.2''$ and $6.4''$ at $100\ \mu\text{m}$ and $160\ \mu\text{m}$, respectively. Therefore, a correction factor for correlated noise is not required and in addition there are sufficient numbers of apertures. Details of the noise measurement using multiple apertures can be found in Eiroa et al. (2013). For all three PACS bands a calibration uncertainty of 5% was assumed (Müller et al., 2011). It dominates in nearly all cases the total measured uncertainty of the target. An exception are the faintest sources with a flux density of less than $\sim 150\ \text{mJy}$ at $100\ \mu\text{m}$. Here, the sky noise can make a larger contribution to the total uncertainty in some cases.

The SPIRE flux densities were measured with aperture radii of $22''$ at $250\ \mu\text{m}$, $30''$ at $350\ \mu\text{m}$ and $42''$ at $500\ \mu\text{m}$. In contrast to the PACS instrument the sky background and r.m.s. were estimated by the usage of a sky annulus between $60''$ – $90''$, which was centered in the source position, while a calibration uncertainty of 7.5% ⁴ was assumed for the three SPIRE bands.

As mentioned above, the resulting flux densities were compared with the ones reported in the literature if they were available. They agree within a $\sim 10\%$ range and thus, the derived flux densities of the K-stars, where no literature values exist can be used reasonably well. For all other targets the values were taken from the literature, since they are the result of detailed individual analysis rather than this more general approach given here. The photometric data can be found in Table A.2.

5 Resolved disc radii

In the last chapter we selected 39 well resolved debris discs which shall form the basis of our statistical analysis. Nevertheless, we cannot start the SED modelling, since we do not know the disc radii. These are necessary to break the notorious degeneracy between radial and dust grain size parameters and thus we use the resolved images of each disc and identify the disc radii with the location of the maximum surface brightness. Furthermore, we assume that each disc ring is confined to a narrow annulus with an eccentricity equal to zero and a width of $\pm 1\%$ of the derived radius. For an Edgeworth-Kuiper-belt like dust ring (see Figure 1.1) the small width is understandable, since the region of the underlying planetesimal belt shelters the most emitting dust and is expected to be relatively narrow (e.g., Kennedy and Wyatt, 2010). In case of the warm component this assumption is necessary, since the flux densities and the photospheric subtraction in the mid-infrared possess large uncertainties.

The question now is what kind of images and which wavelength band should be taken to derive the disc radii. The decision fell on the *Herschel*-PACS¹ images (Poglitsch et al., 2010), since many debris discs could be resolved in at least one PACS band. This is important for the statistical purpose of this work, which requires homogeneity in terms of observational technique in order to avoid systematic discrepancies.

5.1 PACS images

The PACS instrument of *Herschel* (Pilbratt et al., 2010) allows the usage of three different wavelength bands, namely 70 μm , 100 μm and 160 μm . An example for a typical image is given in Figure 5.1, where the object HD 218396 (HR 8799) is shown in all three bands. From 70 μm to 160 μm the beam size is increasing, which means that the best angular resolution can be reached at 70 μm . At this band the disc radii can be derived with the best accuracy possible with PACS. On the other hand the 160 μm band can detect colder dust particles, referring to Wien's displacement law (Wien, 1896). Due to the size dependence of the grain temperature (see Figure 2.6) the colder particles are assumed to be larger in size. The larger grains are less affected by stellar radiation and have a low β value (see Section 2.2.2). Thus they better trace their parent planetesimals. We finally chose the 100 μm wavelength band, since it is the best compromise between the best angular resolution at 70 μm and the possibility of detecting the largest grains at 160 μm . Furthermore, for most of the discs the peak of the excess emission lies in the wavelength range of 100 μm . This minimises the stellar influence of the measured flux densities in this band. For the objects HD 9672 (49 Cet), HD 92945, HD 128311, HD 192263, HD 197481 (AU Mic) and HD 216956 (Fomalhaut) no *Herschel*/PACS images were taken at 100 μm . Therefore, 70 μm images are used to derive the disc radii for these targets.

The location of the maximum surface brightness is inferred from the peak of the source brightness profile measured by fitting a two dimensional Gaussian to the target. The values of FWHM are often given in the literature, but for this work they were recalculated. One reason for the recalculation is the care for comparability and homogeneity of the results by treating all objects the same way. A second reason is the lack of FWHM-values for some debris discs in the literature. At time of this writing some objects had no published data and in addition some data were only given in a reduced way. For

¹Photodetector Array Camera and Spectrometer

Figure 5.1: PACS images of HD 218396 in the 70 μm band (left), the 100 μm band (middle) and the 160 μm (right). The white circles in the bottom left corner of each panel show the beam size of the PACS bands. The pixel size is 1'' for 70 μm and 100 μm and 2'' for 160 μm . From: Matthews et al. (2014a).

instance, the point spread function (PSF) of PACS was already subtracted from the image and the method to derive the disc radii described in the next section would subtract the PSF for a second time and thus lead to wrong results.

5.2 Method description

The method to derive the disc radii from the resolved (PACS-) images was invented by Alexander Krivov (University of Jena) and Jonathan Marshall and works in the following way. A grid of fiducial discs is considered at a distance $d = 20$ pc from the observer. The outer disc radii vary between 10 and 210 AU with all in all 11 different values. The model ring width is supposed to be 10 AU, which is roughly consistent with the assumption of $\pm 2\%$ ring width for the sample (e.g., Strubbe and Chiang, 2006; Chen et al., 2006; Thébault and Augereau, 2007). Two extreme inclinations are assumed, namely face-on (0°) and edge-on (90°), but in general, the inclination of a disc is not well constrained (e.g., Booth et al., 2013; Greaves et al., 2014a). Therefore the chosen ones will deliver an upper and lower limit of the discs radii.

The signal-to-noise ratio (SNR) of the source influences the measured extent of the disc models in the grid. In order to test its degree of influence, the fiducial disc images are combined with a Gaussian noise component, covering a SNR-range from 5 to 100 considering the peak of the source. The lower SNR value represents the minimum necessary for the detection of the disc, whereas the upper value is chosen to mimic an “infinite” SNR which is limited by calibration uncertainties of the absolute flux density. It lies at $\sigma \sim 5\%$ for PACS (Balog et al., 2013). Using the definition of $\text{SNR} = F_\nu/\sigma$ the calibration uncertainty corresponds to a SNR of 20. On the other hand, the relative brightness of the disc compared to the root mean square of the background can be higher than 20. Hence, to cover all plausible disc extents, the upper value is set to 100.

Now, synthetic images of the discs at 100 μm are produced, for which the total disc flux density is set to 0.5 Jy. Looking at the flux densities of the sample of 39 resolved discs this is a good estimate, but here, we are using the brightest discs, i.e. the top end of the brightness distribution of debris discs and thus the model value chosen is not a typical value. The Edgeworth-Kuiper belt for instance is expected to have a flux density of 0.2 mJy at 100 μm which is an order of magnitude less than 0.5 Jy (e.g., Vitense et al., 2012; Bryden et al., 2009; Moro-Martín et al., 2015). However, since the effects of

SNR and the star-to-disc relative brightness are of interest and not the absolute brightness, the total disc flux density is not of importance.

The next step is the convolution of the disc models with the PSF of the PACS/100 band calibrated with the star α Boo. Furthermore, a stellar contribution is added at different $F_{\text{star}}/F_{\text{dust}}$ levels at 100 μm between 0 and 1. The resulting source brightness profiles are fit with a 2D Gaussian profile in order to find the FWHMs of the convolved synthetic images in the long-axis direction.

The final result is a grid of fiducial discs giving the FWHM as a function of R_{disc}/d , orientation (edge-on or face-on), SNR and $F_{\text{star}}/F_{\text{d}}$. It is shown in Figure 5.2. Obviously, the SNR has only a

Figure 5.2: Resulting grid of fiducial discs. Left panel: FWHM divided by FWHM at SNR=5 as function of disc radius. Red squares represent SNR=100, blue circles SNR=10 and green triangles SNR=5. The green solid line shows the trend line through the green triangles. Right panel: FWHM as function of disc radius in the edge-on case for different values of $F_{\text{star}}/F_{\text{dust}}$: red squares $F_{\text{star}}/F_{\text{dust}} = 0.001$; green circles $F_{\text{star}}/F_{\text{dust}} = 0.010$; blue triangles $F_{\text{star}}/F_{\text{dust}} = 0.100$. Coloured solid lines show the best quadratic fit through the same coloured symbols.

small influence on the FWHM. The largest deviation of FWHM for SNR=5 and larger SNR lies within 3%. Hence, we will neglect it here. For small disc radii (up to 50 AU) the FWHM is dominated by the PSF of PACS and shows no significant increase with the disc radius. For larger disc radii the FWHM increases linear with it. In order to fit both, the constant and the linear part, we fit the FWHM with a quadratic function, which is shown in the right panel.

After preparing the grid of fiducial discs, the observed 100 μm disc images of the 39 targets of the sample are fit by a 2D Gaussian profile. The resulting FWHM of the long axis is compared to the model FWHM of the grid (see Figure 5.2), which has the selected orientation (face- or edge-on) and the $F_{\text{star}}/F_{\text{dust}}$ -ratio at 100 μm derived from the SED. Now, the inferred disc radius is corrected for the appropriate distance d stemming from HIPPARCOS catalogue (van Leeuwen, 2007). The inclinations of the observed discs vary between face-on and edge-on. Therefore, the mean value of the disc radii for both of these orientations is taken as the “physical” radius of the disc.

5.3 Results

In this section we are going to analyse the results of the method described above and applied to the sample of 39 resolved disc in order to identify possible biases or method constraints. Furthermore, we will investigate the accuracy of this method.

5.3.1 FWHM for major axes

As shown in Figure 5.3 and referring to the sample of 39 debris discs chosen for this work, more luminous stars tend to lie at larger distances from the observer than less luminous stars, while the FWHM of the discs around more luminous stars tend to be smaller than around less luminous stars. A consequence is that discs around A- or F-type stars are often less well resolved than discs around G-type stars, since they are smaller in angular size and therefore the determination of the disc radius could be more uncertain for them.

Figure 5.3: Distance to target (left panel) and long-axis FWHM at $100\mu\text{m}$ (right panel) as function of stellar luminosity. Black circles represent well resolved discs, i.e. discs with $\text{FWHM} > 1.4$ PSF; red squares show discs with $\text{FWHM} < 1.4$ PSF; blue triangles show objects, where $70\mu\text{m}$ images were used to derive the FWHM. Grey-shaded areas correspond to 1.0, 1.4 and 2.0 times the beam size of PACS at $100\mu\text{m}$. Here, $6.7''$ is assumed for the PSF (PACS Observer’s Manual³). Tilted straight lines are log-log best fits through the symbols.

5.3.2 Disc radii

The results of the radius derivation are listed in Table 5.1. The radii are compared with values given in the literature. In general, the derived disc radii are in good agreement with the literature values.

Possible biases

Figure 5.4 depicts the model results which are close to the values reported in the literature. Exceptions are GJ 581, HD 10647 (q^1 Eri), HD 27290 (γ Dor), HD 102647 (β Leo) and HD 172167 (Vega), since here, R_{disc} and $R_{\text{disc}}^{\text{ref}}$ (data from the literature) differ by more than 20%. We now consider a sample size of 37 targets, ignoring HD 166 and HD 192263 which only possess blackbody radii reported in the literature. Hence, the critical value of the correlation coefficient lies at 0.42 (see Chapter 2.3). Values larger than that show a statistically significant correlation. The comparison between radius deviation and stellar luminosity shows no significant trend ($r_{\text{Pearson}} = 0.00$ and $r_{\text{Spearman}} = +0.21$). The same applies to the correlations between radius deviation and FWHM ($r_{\text{Pearson}} = 0.06$ and $r_{\text{Spearman}} = -0.03$) or distance ($r_{\text{Pearson}} = -0.06$ and $r_{\text{Spearman}} = -0.01$), respectively.

This leads to the conclusion that the model does not invoke systematic biases by determining the debris disc radius and therefore it can be used without further constraints on resolved debris discs.

Notes:

Band gives the wavelength of the PACS image in microns and $F_{\text{star}}/F_{\text{d}}$ gives the flux density ratio at the wavelength used. Flux density ratios marked with (*) are set to zero, since for 70 μm no model with stellar influence exists. The disc radii R_{disc} are mean values of the face-on and edge-on values for each star while $R_{\text{disc}}^{\text{ref}}$ are the values reported in the literature cited under References. Radii marked with (**) are blackbody radii. Here, no “true” disc radii are given in the literature.

Radius correlations

The upper left panel of Figure 5.5 suggests that the disc radius is increasing with increasing distance to the host star with a slope of ~ 1.3 . It is understandable, that discs around distant stars and with a small radius cannot be resolved, since their angular size would be smaller than the beam size of the telescope. Hence, the empty right bottom area can be explained by an observational bias. On the other hand, the empty upper left area is not as easy to explain, since the discs in this area should be

Figure 5.4: Upper left panel: The derived disc radius compared to the literature value as a function of stellar luminosity. Upper right panel: The derived disc radius compared to the literature value as a function of FWHM at $100\,\mu\text{m}$. Lower panel: The derived disc radius compared to the literature value as a function of distance. The straight dotted lines represent the constant fit to the symbols and the factor a gives the value for this line. Symbols are the same as in Figure (5.3). The objects HD 166 and HD 192263 were excluded here, since only the blackbody radii of the discs were given.

close to the Sun, should be larger in radius and therefore, should be easily resolvable. A possibility for the lack of such discs is given in the upper right panel of Figure 5.5. Most of the discs in the sample used have a size between 100 AU and 150 AU. Discs with larger radii are rare. So the probability of having discs with large radii in a short distance is very small and the empty area could be explained by a statistical effect due to a small sample size. Another possibility is that stars at a short distance (up to 20 pc) tend towards smaller stellar luminosities, which is shown in Figure 5.3. Hence, there are more low-luminosity stars with large discs in the solar neighbourhood. For such disc images the flux per pixel is too small to be recognised by the telescope, so these discs have too low a surface brightness for detection and therefore, the empty area is explainable by another kind of observational bias.

An interesting correlation is shown as well in the lower panel of Figure 5.5. Here, the inferred disc radii are shown as function of stellar luminosity. They vary between ≈ 40 AU and ≈ 280 AU, but no systematic increase exists. Indeed, the straight dotted line increases with stellar luminosity, however this result strongly depends on a few outliers, such as the two M-stars GJ 581 and AU Mic. The correlation coefficients confirm statistical insignificance ($r_{\text{Pearson}} = 0.52$ and $r_{\text{Spearman}} = 0.32$).

Considering the protoplanetary disc phase, it is assumed that a disc can be roughly divided into three regions: terrestrial planet formation (0-5 AU), giant planet formation (5-20 AU) and Edgeworth-Kuiper belt formation (> 20 AU). In addition, the first two regions are characterisable by condensation

Figure 5.5: Upper left panel: Derived disc radius as a function of distance. Upper right panel: Frequency of the derived disc radii. Lower panel: Derived disc radius as a function of stellar luminosity. The straight dotted lines represent the best log-log fit to the symbols and the factor b gives the value for the slope. Symbols are the same as in Figure (5.3).

fronts (Pontoppidan et al., 2014, and references therein). Therefore, the formation of planets seems to be connected to the location of volatiles and snow-lines. This is supported by our own solar system, where the dry terrestrial planets lie close to the Sun while the icy giant planets are located further out. Hence, temperature-driven processes might play an important role for the planet forming regions, but referring to the absence of a correlation between disc radius and stellar luminosity it seems that the Edgeworth-Kuiper belt region and its final shape in the remaining debris disc depends on more dynamical processes. For instance a detailed collisional modelling of e.g., HD 207129 (Löhne et al., 2012) or Vega (Müller et al., 2010) showed their compatibility with a steady-state collisional cascade in a narrow planetesimal belt (Matthews et al., 2014a). This is supported by many discs giving evidence of narrow dust producing planetesimal rings (Strubbe and Chiang, 2006; Lestrade and Thilliez, 2015; Lagrange et al., 2016). Another dynamical process is the sculpting by planets which causes asymmetries in the disc emission, such as inclined warps, dense clumps or eccentric offsets (Matthews et al., 2014b). The discs around β Pic and Fomalhaut are an example for that. For both, the presence of a planet was predicted (Heap et al., 2000; Kalas et al., 2005; Quillen, 2006) based on their discs asymmetries, while the real planets were found later (Lagrange et al., 2010; Kalas et al., 2008). Furthermore, the proposed dominance of dynamical processes in shaping debris discs is consistent with Marshall et al. (2014b), who find that correlations between stars, discs and planets could be ascribed to dynamical effects rather than initial composition.

Caveats

Due to the large scatter of the disc radii no correlation between the disc radius and the stellar luminosity could be found in the sample. Nonetheless, a weak correlation found in earlier studies is possible (e.g., Eiroa et al., 2013). The scatter seems to be larger for more luminous stars, which may be explained by the fact that for the sample of this work more luminous stars are more distant on average (see Figure 5.3) and hence are less well resolved.

Besides the large scatter, the discs are approximated by a narrow ring with a single radius. This assumption could be too rough for some discs, which have an extended dust distribution. Analysing the disc width of a small sample of large and bright discs in scattered light images, Krist et al. (2012) found the width to vary between 20% and 60% of the ring radius. Furthermore, detailed studies of especially A-stars, such as Vega (Su et al., 2006) or HR 8799 (Matthews et al., 2014a), which were observed in several wavelength bands, reveal the presence of huge halos. These halos are probably composed of small dust grains in weakly bound orbits (Su et al., 2009; Sibthorpe et al., 2010; Löhne et al., 2012; Matthews et al., 2014a) and could lead to an incorrect measurement of the radius of the dust-producing planetesimal belt.

5.3.3 Estimation of errors

The derivation of the debris disc radii is subject to several uncertainties. At first, many debris discs are unresolved in the minor axis direction due to the relatively low spatial resolution of *Herschel* (at 100 μm the PSF is 6.7"). In case of the 39 resolved discs chosen in this work, 12 objects have a FWHM of the minor axis smaller than 1.2 PSF. Therefore, a disc which is closer to edge-on could be mistaken as a face-on disc. In order to avoid this kind of problem we used the radius average between both cases of inclination, since the probability of a discs inclination being between 0° and 90° is much higher than being exactly 0° or 90°, respectively. On average the difference between face- and edge-on radius lies at 10%. Taking only the uncertainty of FWHM into account, the uncertainty of the derived radius is found to be $\sim 1\%$ on average. Another point is the SNR. It has only a little effect on the derivation of the disc radius and for all the discs of the sample it lies above 9 for flux densities at the 100 μm wavelength band. Hence, the uncertainty in the radius derivation due to SNR is $< 1\%$ (see Figure 5.2). The largest influence on the disc radius has the spectral fractional luminosity at 100 μm , which can be seen in Figure 5.2 as well. For most of the targets, it lies above 10, but for 5 objects this value is smaller. If we compare the resulting disc radii of a model with and without the spectral fractional luminosity the uncertainty is found to be $\sim 4\%$ on average. Including the measurement error of the FWHM at 100 μm of $\sim 4\%$ (Kennedy et al., 2012a) and totalising the before mentioned uncertainties of the stellar influence ($\sim 4\%$) and the SNR ($< 1\%$), the estimate of the radius accuracy is $\sim 8\%$.

In Figure 5.4 the derived disc radii show a deviation of $\approx 20\%$ from the values given in the literature. The question is whether this is consistent with an estimated radius accuracy of $\sim 8\%$. Therefore, we assume an uncertainty of the reference disc radii of $\sim 5\%$ based on values given by Booth et al. (2013). This seems appropriate since only a minority of radii stemming from the literature is given with uncertainties and the largest part of it was analysed by Booth et al. (2013) with 9 discs. Now, we compute the largest possible difference of the estimated and the reference radius. Assuming the reference radius is smaller compared to the derived one, than the reference radius is scaled down by 5% while the derived one is scaled up by 8%. The resulting new deviation of derived and reference radius lies on average at $\sim 26\%$, which is consistent with Figure 5.4.

6 Fitting results using the modified black-body and size distribution method

In the last chapter we analysed the debris disc sample considering the resolved disc radii. This part did not include any fitting of SEDs. On this we will catch up in this chapter. The beginning is made by the occurrence of one- and two-component systems. Then, we investigate possible correlations between the stellar luminosity and the disc temperature, the dominant grain size and the size distribution index or the opacity index, respectively. The best fit parameter values for the sample are given in the Tables 6.3 and 6.4 (SD method assuming pure astrosilicate).

Statistical values

In the further analysis of correlations between different debris disc parameters the number of resolved discs can variate. For example, the blowout grain size does not exist for all 39 targets chosen and so only 32 objects are taken into account in case of astrosilicate. Since we will use the correlation coefficients as a criterion for significant correlations Table 6.1 gives the critical values for different sample sizes.

Table 6.1: Critical values for statistical significance with a significance level of 0.01

Sample size	t_{critical}	r_{critical}
39	2.7154	0.408
37	2.7238	0.418
32	2.7500	0.449
31	2.7564	0.456
25	2.7969	0.504

6.1 Systems with one or two components

The Solar systems debris disc possesses not only the Edgeworth-Kuiper belt, but also the warmer Asteroid belt. Therefore, it is possible that discs around other stars are composed of two components as well. This work is concentrating on the outer Edgeworth-Kuiper belt like component though it is necessary to identify possible second asteroid belt like components in order to fit the disc SEDs properly. Using the criteria given in Chapter 3, Table 6.2 shows the results of this analysis. Pure astrosilicate is used as SD dust composition. A sublimation temperature of 1300 K is assumed as third criterion for both, the MBB dust material and the astrosilicate for reasons of comparability (e.g., Lamy, 1974; Defrère et al., 2011; Kobayashi et al., 2011).

In the sample of 39 resolved debris discs 23 discs reveal a second, warm dust component using the MBB method, whereas 21 discs do that using the SD method. These are roughly 59% or 54% of the sample respectively, which is in agreement with similar studies done before (e.g., Ballering et al., 2013; Chen et al., 2014). Figure 6.1 shows that a warm component can be present around low-luminosity

Notes:

(1) The sublimation radius, R_{sub} , and the radius of the warm component, R_{warm} , are given in AU. A sublimation temperature of 1300 K is assumed. (2) The columns IRS22, WISE22, MIPS24 and IRS31 give the “excess” in units of σ . That means the observed flux density minus the flux density of the cold component minus the flux density of the stellar photosphere. (3) If there is no significant MIR-excess, the objects were fitted with only a one-component model. For these objects no $\chi^2_{\text{one}}/\chi^2_{\text{two}}$ and R_{warm} are given. (*) With a more detailed analysis, including the full IRS spectra and other identification criteria than these given here, the object shows a existence of a warm component (Lebreton et al., 2013; Su et al., 2013b).

stars as well as around high-luminosity stars. For the MBB-method, 27% of all GKM-stars, 43% of all F-stars and 81% of all BA-stars analysed in this sample reveal a second component. This is comparable to the result given in Chen et al. (2014), where 45% of GKM-stars analysed, 69% of F-stars and 78% of BA-stars do that. The results given by the SD-method show similar frequencies except for the GKM-stars, where only 9% of the targets were found to reveal a second component with the criteria chosen. The differences between MBB, SD and the results found by Chen et al. (2014) can be explained by the different fit methods (Chen et al. (2014) used the BB method). Furthermore, the sample given by Chen et al. (2014) contains more targets. In general, both (MBB and SD) lead to similar but not identical results, which can be seen in Figure 6.2. Here, the SEDs of a typical one-component system (HD 50571) and a typical two-component system (49 Cet) are shown, for which both methods give equal results.

Figure 6.1: Frequency of a second component as a function of stellar spectral type. The sample used in this work contains in total 11 GKM-stars, 7 F-stars and 21 BA-stars. Green bars show results given by Chen et al. (2014), where 117 GKM-stars, 158 F-stars and 218 BA-stars were used.

However, with AU Mic another system is given, where a warm component may be present in case of the MBB method or absent in case of the SD method. An explanation for this is that the shape of the SED depends on the fitting method and shows different responses to the variation of fit parameters. The SED of the MBB model represents a Planck curve for $\lambda < \lambda_0$ while for the Rayleigh-Jeans part, where $\lambda > \lambda_0$, the decrease is steeper than for a normal blackbody. Therefore, a SED generated with MBB is narrower than a SED generated with a pure blackbody model. Furthermore, both wavelength parts are separated at λ_0 , where an “artificial knee” can be seen in the SED. On the other hand, the SD model uses different sized particles and thus a temperature distribution and so allows smooth SEDs with both narrower and broader shape than a Planck curve with only one temperature (see Figure 6.2 bottom panels).

6.2 Dust temperatures and disc radii

6.2.1 Dust temperature

Definition

The first question arising from the fit is how to define the temperature of the debris disc in order to analyse possible temperature trends. Although small, the disc has a radial extension and should be warmer at the minimum radius and colder at the outer radius respectively. Furthermore, a size distribution of dust grains is assumed, which leads to different equilibrium temperatures in the stellar radiation field (see Figures 2.6 and 2.7). Hence, in order to describe a disc an effective temperature is necessary, which is in general not the same as the physical temperature of dust grains. The SONATA code (SEDUCE code with fitting tool (Müller et al., 2010)) used for both fitting methods requires the equality of the effective temperature derived from the SED and the dust grain temperature for the MBB method. Therefore, it gives a self-consistent solution in the MBB-case. However, there are several ways to define the disc temperature in case of the SD method. A possibility is using the physical temperature of the dust grains which is averaged over the grain sizes and weighted by the

Figure 6.2: SEDs of HD 50571 (top), 49 Cet (middle), and AU Mic (bottom). Left panel: MBB method; right panel: SD method. Green filled circles with error bars show measured flux densities with their uncertainties.

contribution of particles to the total cross section of the disc. Nevertheless, we decided to use another definition in this work. We measure the wavelength of the discs maximum flux density, λ_{max} , apply Wien's displacement law (Wien, 1896) and define the disc temperature as $T_d \equiv 5100 \text{ K} (\mu\text{m}/\lambda_{\text{max}})$.

Resulting correlation

The dust temperature as function of stellar luminosity is depicted in Figure 6.3 and shows a significant trend ($r_{\text{Pearson}} = 0.70$ and $r_{\text{Spearman}} = 0.70$). For the MBB method it increases from about 30-50 K for low-luminosity stars to 60-100 K for high-luminosity stars. Other *Herschel*-based studies,

Notes:

(1) The disc radii are given in AU, the temperatures in K and $\lambda_0/(2\pi)$, s_{blow} in μm , the fractional luminosity in 10^{-5} . (2) For the values of s_{blow} the simplified equation of Burns et al. (1979) (see Equation (2.16)) was used with a material density of $\rho = 3.3 \text{ g/cm}^3$ and $Q_{\text{pr}} = 1$. For stars with a luminosity less than $1 L_{\odot}$ no blowout size is assumed. (3) The warm component is treated as blackbody. Therefore, the given R_{disc} and T_d are blackbody radius or temperature, respectively.

especially Booth et al. (2013) and Thureau et al. (2014), found similar results for A-stars for which the temperatures lie between 70 and 120 K or 40 and 290 K respectively. In contrast to that, Morales et al. (2011) used *Spitzer* data and give a median value for their sample of G-stars of 59 K while their sample of A-stars is given with 62 K. The trend found in this work is stronger compared to Morales et al. (2011), but roughly consistent as well.

In case of the SD method, the temperature increases with increasing stellar luminosity from 20-60 K to 50-120 K, but in contrast to the MBB method, the increase is not as steep, while in general the discs are slightly warmer. Nevertheless, the correlation is significant ($r_{\text{Pearson}} = 0.59$ and $r_{\text{Spearman}} = 0.56$).

6.2.2 Dust-to-blackbody-temperature ratio

Now, the disc temperature, T_d , is compared to the temperature a disc made of pure blackbodies would have (T_{BB}). Figure 6.4 shows a clear decrease of the temperature ratio with increasing stellar luminosity. The result of the MBB method shows a linear trend for the whole luminosity range

6. FITTING RESULTS USING THE MODIFIED BLACKBODY AND SIZE DISTRIBUTION METHOD

Table 6.4: Fitting results for the SD method

Notes:

(1) The disc radii are given in AU, the temperatures in K and s_{min} , s_{blow} in μm and the fractional luminosity in 10^{-5} . (2) For the values of s_{blow} the equation of Burns et al. (1979) (see Equation (2.16)) was used with a material density of $\rho = 3.3 \text{ g/cm}^3$. Q_{pr} was averaged over the stellar spectrum. (3) The warm component is treated as blackbody. Therefore, the given R_{disc} and T_{d} are blackbody radius or temperature, respectively.

($r_{\text{Pearson}} = -0.63$ and $r_{\text{Spearman}} = -0.66$), while the SD result reveals that the trend is flattening for low-luminosity stars ($r_{\text{Pearson}} = -0.59$ and $r_{\text{Spearman}} = -0.66$). This is reported in the literature as well (Booth et al., 2013). The temperature ratios for stars with a stellar luminosity smaller than the Sun's are smaller than expected by the log-log trend chosen, whereas it is a good approximation in the MBB case. A possible reason are the absorption properties of the small astrosilicate grains depicted in Figure 2.3. Here, the absorption efficiency drastically decreases in the visible wavelength range. Hence, the smallest particles become colder (Krivov et al., 2008) than grains slightly larger and in case of low-luminosity stars, such as GJ 581 or HD 128311, this leads to smaller temperature ratios.

6.2.3 Dust-to-blackbody-radius ratio

In Chapter 5, we discussed a possible correlation between the resolved disc radius and the stellar luminosity. Therefore, the disc radius should now be compared to the blackbody radius of a debris disc, analogue to the temperature considerations before. Here, the blackbody radius is the radius

Figure 6.3: Dust temperature as a function of stellar luminosity. Left: MBB method; right: SD method. Open and filled symbols represent one- and two-component disc systems. Circles stand for well-resolved discs, squares for marginally resolved ones. Blue asterisks are objects, where no (sub-) millimetre detections exist. The line shows the best linear log-log-fit to the data points.

Figure 6.4: Dust to blackbody temperature ratio as a function of stellar luminosity. Left: MBB method; right: SD method. Open and filled symbols represent one- and two-component disc systems. Circles stand for well-resolved discs, squares for marginally resolved ones. Blue asterisks are objects, where no (sub-) millimetre detections exist. The line shows the best linear log-log-fit to the data points.

which a disc at a certain temperature made of pure blackbodies would have.

At the “true” disc radius, R_{disc} , the dust has an effective temperature, T_d . If we assume that the dust can emit like a blackbody, a blackbody temperature, $T_{\text{BB}}(R_{\text{disc}})$, exists as well. Using Equation (2.29) it is obvious that $R_{\text{disc}} \propto T_{\text{BB}}^{-2}(R_{\text{disc}})$. On the other hand, the dust has a certain effective temperature at a certain disc radius. Assuming blackbody grains again, there is of course a blackbody radius, $R_{\text{BB}}(T_d)$, for which Equation (2.29) is also valid and leads to $R_{\text{BB}}(T_d) \propto T_d^{-2}$. Therefore, by analysing the trend of T_d/T_{BB} , we can analyse the radius ratio as well since

$$\frac{R_{\text{disc}}}{R_{\text{BB}}(T_d)} = \frac{T_{\text{BB}}^{-2}(R_{\text{disc}})}{T_d^{-2}} = \left(\frac{T_d}{T_{\text{BB}}} \right)^2 \equiv \Gamma. \quad (6.1)$$

The result is that the dust-to-blackbody-radius ratio decreases with increasing stellar luminosity, like

the temperature ratio does. A similar study was done at first for A-stars by Booth et al. (2013) who found Γ decreasing from about 2.5 to 1.0 in a luminosity range between 10 and 100 L_{\odot} . This was followed by a study from Morales et al. (2013) who used a larger sample over a broader luminosity range and included the targets from Booth et al. (2013). They found Γ decreasing from about 9 at $L \approx 0.01 L_{\odot}$ to 4 at $L \approx 1 L_{\odot}$ and 1 at $L \approx 100 L_{\odot}$.

Knowing the correlation between Γ and the stellar luminosity, a possibility of estimating the “true” disc radius of an *unresolved* debris disc opens up. The detailed description of this method can be found in Chapter 8.

6.2.4 Fractional luminosities and disc radii

The correlation between fractional luminosity and disc radius was investigated and there seemed to be a trend between both parameters. In order to explain this, the role of fractional luminosity as lower limiting case for observations and as upper limiting case for collisional evolution is taken into account (see Chapter 2). In Figure 6.5 the upper grey areas show the maximum fractional luminosity for three

Figure 6.5: Fractional luminosity as a function of disc radius. Left: MBB-method; right: SD-method. Black circles show well resolved objects with an FWHM > 1.4 PSF; red squares show objects with an FWHM < 1.4 PSF and blue triangles show objects where the radii were derived from 70 μ m images. The straight dotted line is the best log-log fit through the data points and the grey areas give the areas for the maximum and minimum fractional luminosity possible for a star of 1 L_{\odot} (dark grey), 3 L_{\odot} (middle grey) and 15 L_{\odot} (light grey). Further explanation see in the text.

stars of 1 L_{\odot} , 3 L_{\odot} and 15 L_{\odot} calculated by Equation (2.41). All three stars are assumed to have an age of 30 Myr. The grey areas show a clear increase with the disc radius and thus, a correlation of fractional luminosity and disc radius could be justified with the model of maximum fractional luminosity. The lower areas give the minimum fractional luminosity necessary in order to detect the debris disc. The same stellar luminosities were used and a minimum flux density of $F_{\nu} = 5.5 \text{ mJy}^1$ was assumed for PACS at 100 μ m. Here, an increase of the fractional luminosity with increasing disc radius could be justified as well. And indeed, the targets lie in the area between maximum and minimum fractional luminosity. However, the correlation coefficients do not confirm the correlation (MBB: $r_{\text{Pearson}} = 0.34$ and $r_{\text{Spearman}} = -0.37$; SD: $r_{\text{Pearson}} = 0.31$ and $r_{\text{Spearman}} = 0.34$) due to the strong scatter of the stellar luminosity of the targets.

Wyatt et al. (2007a) applied their model to a sample of Sun-like stars and found the fractional luminosities measured for these systems to be much higher than the expected maximum fractional

¹PACS Observer’s Manual, Version 2.5.1; http://herschel.esac.esa.int/Docs/PACS/html/pacs_om.html

luminosities. An explanation was the transience of dust produced in stochastic processes, e.g., the collision of two massive protoplanets (Song et al., 2005) the sublimation of a supercomet (Beichman et al., 2005) or the sublimation of a swarm of comets (Gomes et al., 2005). In our sample of resolved discs no evidence for such processes could be found since all fractional luminosities lie below the expected maximum fractional luminosities.

6.3 Grain sizes

After analysing the disc temperatures and radii we now come to the grain sizes. We will start with an investigation of the blowout grain size, which is followed by the minimum grain size or characteristic grain size respectively.

6.3.1 Blowout grain size

As defined in Chapter 2, the blowout grain size of a certain dust material is reached, when β of Equation (2.16) is equal to a value of 0.5. The parameter β depends on the stellar luminosity, the stellar mass, the bulk density of the dust material and the radiation pressure efficiency. For low-luminosity stars, β never reaches this value and thus no particles are expelled from the circumstellar system due to radiation pressure. In Figure 6.6 the β -parameter is shown as a function of grain size.

Figure 6.6: β -parameter as a function of grain size. The red dotted line represents GJ 581, the orange small dotted line HD 166, the green dash-dotted line HD 104860 and the blue small dash-dotted line HD 9672. The solid black line lies at a value of 0.5. Pure astrosilicate was used, except for HD 166, where a mixture of astrosilicate and ice was applied.

For all objects represented here, β reaches a maximum value at a certain grain size and becomes constant towards smaller grain sizes. Towards larger sizes it continues to decrease. For GJ 581, the object with the lowest luminosity in the sample, β lies always below 0.5 and thus no blowout grain size exists. In case of HD 104860, which has a luminosity comparable to the Sun, β increases and exceeds the value of 0.5. Then it decreases below 0.5 again. Therefore, two blowout grain sizes exist. The target HD 166 has a smaller luminosity than HD 104860 and here, β reaches 0.5 once at its maximum point. Theoretically, two blowout grain sizes exist here as well, but both lie at the same value. HD 9672 (49 Cet) is a high-luminosity target. The constant value of β at small grain sizes

lies above 0.5. Towards larger sizes, it decreases and falls below 0.5 for the first time. As a result, there is only one blowout grain size for this object. In general we can say that objects with lowest luminosities do not owe a blowout grain size, while targets with moderate stellar luminosity possess two of them. In contrast, the high-luminosity objects only have one blowout size. In Figure 6.7 the resulting blowout sizes are given for the sample of 39 resolved debris discs. Some apparent outliers

Figure 6.7: Blowout grain size, multiplied with $(M/M_{\odot})/(L/L_{\odot})$ as a function of stellar luminosity. Different colours correspond to different dust compositions, as indicated in the legend. Symbols with connecting solid lines: results for size- dependent Q_{pr} obtained with Mie-theory and for actual stellar masses from Table 4.2; horizontal dashed lines results for $Q_{\text{pr}} = 1$ and assuming the main-sequence mass-luminosity relation. The vertical offset between the symbols and lines that represent different compositions is caused by their different bulk densities (see Table 2.1). For stars with $L_{\odot} \lesssim L \lesssim 10L_{\odot}$, except for pure carbon, the second blowout limit appears in the bottom part of the plot. Grains in blowout orbits are those between the upper and lower branches. For the low-luminosity stars in the sample (HD 92945, HD 128311, HD 131511 and HD 192263 with $L < 0.49L_{\odot}$) the upper blowout limit only exists for carbon and the mixture carbon and astrosilicate, while the lower blowout limit does only exist for astrosilicate and carbon. The strongest outliers amongst the symbols are stars with masses departing from the main-sequence mass-luminosity relation. These are the A1-subgiant β UMa with $L/L_{\odot} = 58.2$ and the close binaries α CrB ($L/L_{\odot} = 57.7$) and the A1III-star β Tri ($L/L_{\odot} = 73.8$).

reflect the fact that s_{blow} for any individual star depends on Q_{abs} and Q_{sca} averaged over the stellar photospheric spectrum of that particular star. For example, κ CrB with $L/L_{\odot} = 12.5$ is a K1-subgiant with a temperature twice lower than that of its neighbouring stars in the figure. This results in the larger averaged values of Q_{abs} , Q_{sca} , and s_{blow} compared to its neighbours. For still other stars and particular grain compositions, the stellar spectrum peaks at the maxima of the resonant oscillations of

the Mie-calculated Q_{abs} and Q_{sca} , which also makes s_{blow} different from that of the adjacent stars. This is particularly the case for β Leo with $L/L_{\odot} = 13.2$, if the astrosilicate-ice and astrosilicate-carbon mixtures are assumed (Pawellek and Krivov, 2015).

6.3.2 Minimum grain size

The next dust parameter investigated was the minimum grain size or characteristic grain size respectively. Our expectation was that it would increase with increasing stellar luminosity, like the blowout grain size (see Equation (2.16)) does. As shown in Figure 6.8 the results of the MBB method lead to

Figure 6.8: Minimum grain size as a function of stellar luminosity. Left: MBB method; right: SD method. Symbols are the same as in Figure 6.3. The green line shows a constant fit to the symbols of the SD method.

such an increase ($r_{\text{Pearson}} = 0.46$ and $r_{\text{Spearman}} = 0.47$), whereas the SD method with pure astrosilicate gives a much weaker trend ($r_{\text{Pearson}} = 0.54$ and $r_{\text{Spearman}} = 0.36$), which is also consistent with a constant grain size of roughly $5 \mu\text{m}$.

Considering the MBB result there are many objects for which the characteristic grain size is smaller than $1 \mu\text{m}$ and thus smaller than the shortest wavelength of $10 \mu\text{m}$ used for fitting. It is thinkable that for such objects the λ_0 cannot exactly be determined, since it lies not in the wavelength range of the SED, but nevertheless it is possible. Here, for all wavelengths included in the fitting process, a decrease of the absorption efficiency is assumed due to $Q_{\text{abs}} = (\lambda/\lambda_0)^{-\beta_{\text{mod}}}$, while λ_0 gives the starting point and β_{mod} the steepness of the decrease. Thus, the absorption efficiency is clearly defined for all λ_0 , but since the cutoff wavelength lies not in the wavelength range of the disc’s SED no artificial “knee” can be seen in it.

We assume the relation $\lambda_0 = 2\pi s_{\text{min}}$ given in Backman and Paresce (1993) for the grain sizes derived from the MBB method. To check whether this is a good estimate we compared the dominant grain sizes of both methods with each other (see Figure 6.9). If the characteristic grain size is $0.01 \mu\text{m} < \lambda_0/(2\pi) < 0.1 \mu\text{m}$ the minimum grain size, s_{min} differs more than one magnitude from the MBB result for most of the targets. This deviation decreases for larger s_{min} . This means if the characteristic MBB grain size is smaller than $1 \mu\text{m}$ the correlation between λ_0 and s_{min} is less reliable.

6.3.3 Minimum-to-blowout grain size ratio

The blowout grain size increases with increasing stellar luminosity (see Equation (2.16)) and it was expected that the dominant dust grain size behaves in a similar way. However, we found that at least

Figure 6.9: Characteristic grain size of the MBB method as a function minimum grain size of the SD method with pure astosilicate. The solid black line shows where $\lambda_0/2\pi = s_{\min}$.

for the SD method with pure astosilicate the grain size shows a trend which is not as steep as it should be. In Figure 6.10 the ratio of the minimum grain size and the blowout grain size is given as a function

Figure 6.10: Characteristic grain size of the MBB method (left) and minimum grain size of SD method (right) in units of the blowout grain size as a function of stellar luminosity. Symbols are the same as in Figure 6.3.

of stellar luminosity. Since the blowout grain size does not exist for the low-luminosity targets, the sample contains now 32 objects. There is a clear decrease towards higher luminosities from ~ 10 for solar-type stars to unity for A- and B-type stars in the SD method. Since the MBB method shows a stronger correlation between characteristic grain size and stellar luminosity the trend of the grain size ratio is statistically insignificant ($r_{\text{Pearson}} = -0.04$ and $r_{\text{Spearman}} = -0.13$), while for the SD method it is the strongest correlation found in this work ($r_{\text{Pearson}} = -0.81$ and $r_{\text{Spearman}} = -0.77$). As explained before, there are some objects for which the characteristic grain size of the MBB method is very small and hence a bad estimate for the minimum grain size. If the objects with such small characteristic particle sizes are excluded 25 targets with luminosities between $0.6 L_{\odot}$ and $74 L_{\odot}$ remain in the sample and the correlation turns out to be significant now ($r_{\text{Pearson}} = -0.83$ and $r_{\text{Spearman}} = -0.54$). There is

a trend from ~ 10 for solar-type stars to unity for A- and B-type stars as well, however the correlation is not as strong as for the SD method.

Although this trend was first reported in Pawellek et al. (2014) previous studies confirm the deviation of the minimum grain size from the blowout grain size for individual debris disc systems (Su et al., 2009; Krist et al., 2010; Golimowski et al., 2011; Kirchschlager and Wolf, 2013; Morales et al., 2013) and even the decrease with increasing stellar luminosity can be found combining the results of the individual systems. Nevertheless, this trend was not expected by theory. Therefore, we investigated several possibilities in order to explain it. These are described in Chapter 7.

6.4 Opacity index and grain size distribution index

We now come to the size distribution index or the opacity index, respectively. In Figure 6.11 these parameters are presented as a function of stellar luminosity. The opacity index varies between 0 and 2.5, while for the most discs it lies between zero and unity. Previous studies (e.g., Williams and Andrews, 2006; Nilsson et al., 2010) show similar results. There seems to be a trend of β_{mod} increasing with the stellar luminosity, However, this is not confirmed by the correlation coefficients ($r_{\text{Pearson}} = 0.21$ and $r_{\text{Spearman}} = 0.26$). As well there seems to be a slight increase of the size distribution index with

Figure 6.11: Opacity index (left) and size distribution index (right) as a function of stellar luminosity. The symbols are the same as in Figure (6.3).

the stellar luminosity, but here the correlation coefficients do not confirm this as well ($r_{\text{Pearson}} = 0.32$ and $r_{\text{Spearman}} = 0.28$). The q -parameter varies between 2.8 and 6.5, although for most targets it lies between 3 and 4. A value of 3.5 is predicted by theory (Dohnanyi, 1969) and other studies show similar results for individual objects (e.g., Augereau and Beust, 2006; Donaldson et al., 2013; Lebreton et al., 2013). Compared to Pawellek et al. (2014) the largest values of 6.5 are even larger than the 5.5 reported there. The reason is an improvement in the fitting algorithm which led to smaller χ^2 . Such large q -values were reported in the literature before (e.g., Ertel et al., 2012; Riviere-Marichalar et al., 2014). Ertel et al. (2012) even found values of 9 for HD 199260 or 10 for HD 206860, respectively. They stated that these debris discs show evidence for a deviation from the standard equilibrium collisional cascade, however, the results depend very much on the photometric data reduction pipeline used.

In order to investigate a possible correlation between the dominant grain size and the size distribution or opacity index respectively, we analysed the fit parameter space and generated χ^2 -maps for different objects.

6.5 χ^2 -maps

In this section the spatial distribution of χ^2 in the parameter space is analysed. Figure 6.12 gives typical χ^2 -maps for stars with different stellar luminosities, which were generated for both, the MBB and SD method. The lines of equal χ^2 are elongated from the bottom left to the top right, which

Figure 6.12: χ^2 -maps for HD 50571 (left), HD 142091 (middle) and HD 216956 (right) in the MBB (top) and SD (bottom) method. The lines show the $n \times \chi_{\text{red}}^2$ isolines for $n = 1$ (small circle), $n = 2$ (yellow line), $n = 3$ (red line), $n = 4$ (blue line) and $n = 5$ (black line), where χ_{red}^2 is the best-fit value.

can be explained as follows. If the grain size (λ_0 or s_{min}) is larger than the best-fit value, the fitting routine is forced to take a steeper size distribution given by a larger size distribution index (β_{mod} or q). As well the shape of the isolines can be understood, while we will concentrate on the SD method here. We assume that the emission of different sized grains is proportional to their cross section as a rough estimate and define an “effective” grain size, s_0 . This grain size is the one for which we replace the size distributed grains with the same number of equal-sized grains of radius s_0 . Furthermore, we require that the equal-sized grains have the same cross-section as the size distributed ones. This can be described by

$$\int_{s_{\text{min}}}^{\infty} s^{2-q} ds = s_0^2 \int_{s_{\text{min}}}^{\infty} s^{-q} ds. \quad (6.2)$$

Additionally, we assume that $q > 3$ which leads to

$$s_0 \approx s_{\text{min}} \sqrt{\frac{q-1}{q-3}}. \quad (6.3)$$

Taking $q = 3.5$ for instance the “effective” grain size would be $\approx 2.2s_{\text{min}}$. An expectation now is that different pairs of (s_{min}, q) with the same s_0 lead to the same SEDs that reproduce the observed one equally well and thus the isolines should roughly follow the equation

$$s_{\text{min}} \sqrt{\frac{q-1}{q-3}} = \text{const.} \quad (6.4)$$

Indeed, this can be seen in Figure 6.12. Here, q rises more steeply for larger s_{\min} and the isoline takes a kind of banana shape. Another fact is that the isolines are tilted to the x-axis, whereas this tilt is becoming smaller for stars with a higher stellar luminosity (see panels from left to right). The reason is that the effective grain size is slightly larger around more luminous stars and hence the derivative dq/ds_{\min} is smaller at the same s_{\min} .

6.6 The role of the stellar photosphere

We investigated the stability of the fit results by changing the contribution of the stellar photosphere. Uncertainties of the stellar temperature of ± 100 K and the stellar luminosity of $\pm 20\%$ were assumed and new photospheres calculated using the same models as described in Section 4.2. The changes of each photosphere compared to the original photosphere used for fitting are shown in Figure 6.13. Obviously, the strongest deviations can be found between 0.1 and 0.5 microns, whereas in the longer wavelength range the differences lie below 5%.

Figure 6.13: Flux density of the stellar photosphere of HD 9672 for different stellar luminosities and temperatures divided by the photosphere used for fitting ($L/L_{\odot} = 16$ and $T = 9000$ K) as a function of wavelength.

We chose four different targets, where two stars (a low and a high luminosity one) possess a one-component system while the two others (as well a low and a high luminosity one) are composed of two rings. Then we fit the SEDs of all targets with the four new photospheres. The results are listed in Table 6.5. The cold component fit results derived from the new photospheres show only small deviations from the original parameter values and lie in general within the uncertainties of the original fit (see Table 6.4). Considering the high fractional luminosity targets, HD 9672 (49 Cet) and HD 10647 (q¹ Eri) the standard deviations of grain sizes, dust temperatures and fractional luminosities are of the order of 1-3% while with 3-13% it is larger for the low-fractional luminosity objects, HD 48682 and HD 95418 (β UMa). The cold component has the largest influence in the far-infrared, and here, the stellar photosphere emission is several orders of magnitude smaller than the dust emission. Furthermore, the deviations of each new photosphere lies below 5% in this wavelength range. Thus, we can say that large uncertainties of the stellar parameters have not much influence on the cold component parameters.

On the other hand, the warm component radius is affected more strongly looking at a standard deviation of 8-20%. In the mid-infrared, the contribution of the stellar photosphere to the excess emission is comparable to the dust emission and so it has more influence on the warm component

Table 6.5: Fit results for different stellar photospheres.

HD	T [K]	L/L_{\odot}	s_{\min} [μm]	T_{d} [K]	R_{disc} [AU]	f_{d}

	9130	46.6	5.15	112	...	1.03×10^{-5}
	9230	58.2	4.98	112	...	1.03×10^{-5}

fit results. Nevertheless, the variation of the different stellar photospheres lies below 5% as well. Therefore, the uncertainties of stellar parameters only play a minor role in the SED fitting of debris discs.

7 Analysis of the grain size – stellar luminosity trend

We found a correlation between the dominant grain size in units of the blowout grain size and the stellar luminosity, which is even the strongest trend found in this work (considering the SD method with pure astrosilicate). In order to explain this unexpected result we tried several possibilities starting with a mere fitting effect due to the dust composition used, which is followed by a test for statistical variations of the trend. After checking the possible technical reasons for the correlation found, two physical reasons are tested as well, namely the role of the surface energy constraint and the role of stirring.

7.1 Dust compositions

At first, we analysed the variation of the grain size – stellar luminosity trend by using different dust compositions in order to check the robustness of the resulting trend (see Section 2.1.3). Besides pure astronomical silicate (Draine, 2003a) and pure amorphous carbon (ACAR, Zubko et al. (1996)) we used a 1:1 mixture of astrosilicate and ice (Li and Greenberg, 1998), a 1:1 mixture of astrosilicate and amorphous carbon and a 1:1 mixture of astrosilicate and vacuum, which should mimic porous dust particles. The 1:1 ratios give the volume fraction of each dust component. The sublimation temperatures were assumed to be 1900 K for pure carbon and 130 K for pure ice particles (Kobayashi et al., 2011). However, since the warm component is not well constrained it was assumed as blackbody and we used the original 1300 K of astrosilicate as sublimation temperature for it. Considering the astrosilicate and ice mixture (Table B.1), most of the inner rings should not contain ice particles, since their temperature exceeds the sublimation temperature of ice. This is similar to the Solar system, where the Asteroid belt is located between Mars and Jupiter. Assuming its distance to the Sun of ~ 4 AU and using Equation (8.2) the temperature lies at ~ 140 K and exceeds the ice sublimation temperature as well. If a smaller distance to the Sun is assumed the temperature even increases.

Figure 7.1 shows the resulting temperature and size parameter trends already mentioned in Chapter 6. The steepness of the trends varies with different compositions, but persists in general. This means that for all compositions used the dust gets warmer, the disc radius goes down to the blackbody value, the typical grain size increases not as fast as expected and therefore, the typical grain size in blowout units decreases with increasing stellar luminosity.

Analysing the differences between the dust compositions we recognised the following. For porous particles the s_{\min}/s_{blow} dependence on the stellar luminosity is flatter than for compact particles. This is explainable by looking at Figure 2.6. Considering particles with sizes $s < 3 \mu\text{m}$ the temperature of porous grains is the lowest compared to all compositions used and conversely, for porous particles larger than $3 \mu\text{m}$ the temperature is higher than for other mixtures. Therefore, for discs around early-type stars the temperature of a porous astrosilicate grain of size s_{\min} is higher than that of a compact astrosilicate particle of the same size. Thus, the SED of such a disc can only be reproduced, if the porous grains are larger than the compact ones. Conversely, for discs around late-type stars a porous grain with size s_{\min} is colder than a compact one and therefore, the porous particles must be smaller

Figure 7.1: Various dust and disc parameters as function of the stellar luminosity for different dust compositions: (a) dust temperature, (b) disc's true radius to its blackbody radius, Γ , (c) minimum grain size s_{\min} , (d) grain size ratio, s_{\min}/s_{blow} , (e) size distribution index, q . Different colours denote different dust compositions: astrosilicate+vacuum (black dash-dotted line), astrosilicate+ice (blue dashed line), astrosilicate (red solid line), astrosilicate+carbon (orange dotted line) and carbon (green small-dotted line). Symbols with error bars are fit results for individual discs in the sample. A straight line of a certain colour is a best-fit trend line through the symbols of the same colour.

than the compact ones (Kirchschlager and Wolf, 2013). This results in a steeper trend of the minimum grain size of porous particles with the stellar luminosity, and thus a gentler decrease of the s_{\min}/s_{blow} ratio, compared to the other dust compositions.

The role of porosity

As a result from the analysis of different dust compositions we found that for a mixture of 50% astrosilicate and 50% vacuum (that means 50% porosity) the decrease of the s_{\min}/s_{blow} trend with stellar luminosity could be slightly flattened. The idea now was to increase the degree of porosity in order to erase the grain size ratio trend completely. We assumed 10% astrosilicate and 90% vacuum as a dust composition, which represents an extreme case of porosity, and fit the sample of resolved debris discs again. It turned out that for most of the discs the quality of the SED fits, measured by χ^2 , gets poorer with the increasing degree of porosity. For example, the disc of HD 50571 yields the reduced $\chi^2 = 1.84$ for a porosity of zero (for pure astrosilicate). If the degree of porosity is increased to 50%, χ^2 increases as well to 1.86 and with 90% to 3.06. Another point is that the statistical scatter of the fit results increases as well and therefore the correlation between s_{\min}/s_{blow} and the stellar luminosity gets weaker with increasing porosity. Furthermore, the usage of this dust composition seems questionable, since the values of the fit parameters turn out to differ a lot from the typical values of the other compositions. An example is the size distribution index, which lies in general between 3 and 4 (in extreme cases between 4 and 7). For 90% porosity it changes to values around -2 for some targets, and this means that the size distribution contains more large particles than small ones. Considering the theory of collisional evolution of debris disc systems this index value is not compatible with it (e.g., Dohnanyi, 1969; Williams and Wetherill, 1994; Kenyon and Bromley, 2004c; Löhne et al., 2008; Pan and Schlichting, 2012).

Nevertheless, while this correlation is the strongest one for pure astrosilicate in this work it is statistically insignificant for 90% porosity ($r_{\text{Pearson}} = -0.25$ and $r_{\text{Spearman}} = -0.33$).

All in all we conclude that the decrease of the s_{\min}/s_{blow} ratio with increasing stellar luminosity identified by Pawellek et al. (2014) is pretty robust against the variation of dust composition considering compact dust grains (Pawellek and Krivov, 2015) and the usage of a 90% porosity dust composition is not appropriate for the sample of resolved debris discs.

7.2 Outliers

Since the choice of dust composition does not erase the correlation between grain size ratio and stellar luminosity the influence of individual systems in the resulting trend was investigated in order to check its robustness. Object HD 109085 (η Crv) is an example of such an outlier. By looking at Figure 7.1d it turns out that this target owns a much higher grain size ratio than other objects with comparable stellar luminosities. Furthermore, the uncertainties of HD 109085 are quite small, which could lead to the effect that the resulting best-fit trend line lies above many data points. Other examples for outliers are two of the four most luminous stars, namely HD 172167 (Vega) and HD 13161 (β Tri), as well as HD 104860. These targets have all a high derived minimum grain size and small uncertainties and thus it is possible that they influence the trend of s_{\min}/s_{blow} .

The outliers of the sample were identified in the following way. For the whole sample one data point by one was removed and the best-fit trend line calculated at each time. Then it was analysed which target removal had the largest influence on the regression line. In Figure 7.2 the results for pure astrosilicate are presented. There are three apparent outliers, namely HD 104860, HD 207129

Figure 7.2: Identification of outliers in $s_{\min}/s_{\text{blow}}(L)$ for pure astrosilicate. Left: the factors A and slopes B of the trend lines in the form $A (L/L_{\odot})^B$, calculated by excluding from the sample one data point at a time. Error bars are uncertainties in A and B returned by the fitting. The “cross-hairs” depict the best fit through the whole sample. The strongest outliers are shown in colour: red is HD 104860, light blue is HD 207129, and blue is β Tri. Right: size ratio versus stellar luminosity for pure astrosilicate with and without outliers. The colour coding is the same as on the left. The black line gives the trend line for the entire sample. The line of a certain colour is the best fit without the object of the same colour. The removal of HD 104860 or HD 207129 lead to similar regression lines. Therefore, only the result for the removal of HD 104860 is shown.

and HD 13161 (β Tri). Removing either HD 104860 or HD 207129 the slope of the trend is changed from -0.48 to -0.43. The difference is 0.05 and lies within the uncertainty of the best-fit trend (0.07). On the other hand, if β Tri is removed, the slope is changed more strongly by 0.11 to a value of -0.59. This is larger than the uncertainty given by the fit. All in all we can say that individual systems can influence the best-fit trend line moderately. Therefore, we decided to exclude β Tri from a further analysis of the sample. This object is the most luminous star of the sample and belongs to the giant class. Furthermore, it is a close binary (Kennedy et al., 2012b). These peculiarities suggest that β Tri might not be representative for the whole sample.

7.3 Subsamples

We investigated the technical robustness of the trend by analysing the influence of different dust compositions and individual targets. Now, we assume that the size ratio may depend on more physical parameters of the system, such as the fractional luminosity or the disc radius and thus we will have a more statistical point of view on the robustness.

7.3.1 Extracting and comparing subsamples

We split the whole sample of 31 objects (all targets with blowout grain sizes, minus β Tri) into two subsamples of sizes n_1 and n_2 , where $n = 31 = n_1 + n_2$ according to a physical parameter, P , selected. For instance, one subsample contains objects with a smaller median value of P and the other one all objects larger than the median value of P . In that case, $n_1 = 15$ and $n_2 = 16$. After dividing the sample, we analyse the $s_{\min}/s_{\text{blow}}(L)$ trend for both subsamples individually and calculate the best-fit log-log regression lines with slopes $b_1 \pm SE(b_1)$ and $b_2 \pm SE(b_2)$. The parameter $SE(x)$ represents

the standard error of x . Finally, it has to be checked whether the trends of both subsamples are statistically, significantly different or not. Thus, the null hypothesis is that the two subsamples are not significantly different and the Student's t-score can be applied with

$$t = \frac{|b_1 - b_2|}{SE(b_1 - b_2)} \quad (7.1)$$

and

$$SE(b_1 - b_2) = \sqrt{SE(b_1)^2 + SE(b_2)^2}. \quad (7.2)$$

Then the probability, p , has to be calculated, which proves whether the null hypothesis is true or not with $n_1 + n_2 - 4$ degrees of freedom. The criterion used is that the subsamples are different, if the two-tailed $p < 0.01$.

Since the sample contains a number of 31 objects it is not particularly large. Hence, it is necessary to check the feasibility of this procedure. Therefore, we chose the HD-number of the targets as the parameter P . The number is connected to the right-ascension of the primary stars and as such it is an unphysical parameter, which should lead to a confirmation of the null hypothesis. The visualisation

Figure 7.3: The grain size ratio as a function of stellar luminosity for two subsamples. The subsamples are divided by the HD number. Objects with low HD number are shown in blue squares and objects with high HD number are shown in red circles. The blue and red straight lines are the best fit through the blue and red symbols. The black line represents the best fit for the whole sample.

of the results is given in Figure 7.3. The slopes of both subsamples are -0.53 ± 0.05 and -0.61 ± 0.08 , which leads to a t-value of 0.85 by using Equations (7.1) and (7.2). With 27 degrees of freedom the probability of the null hypothesis is $p = 0.40$. This is much larger than 0.01 and thus, both subsamples are indistinguishable from each other. So, our expectation is confirmed, the null hypothesis accepted and the usage of subsamples is feasible.

7.3.2 Discs of low and high fractional luminosity

In this section the parameter P is identified with the fractional luminosity of the debris discs. The median value of it is $P_{\text{med}} = 6.50 \times 10^{-5}$, whereas the subsample sizes stay $n_1 = 15$ and $n_2 = 16$. The results are presented in Figure 7.4 for both, the minimum grain size and the grain size ratio as function of stellar luminosity. For reasons of comparability with the size ratio plot, the minimum grain

Table 7.1: Comparing the regressions for s_{\min}/s_{blow} in pairs of subsamples for $P < P_{\text{med}}$ and $P \geq P_{\text{med}}$

P	$b_1 \pm SE(b_1)$	$b_2 \pm SE(b_2)$	t-score	p	Verdict
HD	-0.53 ± 0.05	-0.61 ± 0.08	0.85	0.40	same

FWHM	-0.60 ± 0.08	-0.55 ± 0.07	0.47	0.64	same

 Figure 7.4: Minimum size (left) and size ratio (right) vs. stellar luminosity, assuming pure astrosilicate, for the subsamples of low and high fractional luminosity discs. Blue line and squares: $f_d < 6.50 \times 10^{-5}$, red line and circles: $f_d \geq 6.50 \times 10^{-5}$, black line: the entire sample.

size plot does only contain the 31 objects mentioned above, although all targets of the sample own a minimum grain size. The subsamples cover a broad stellar luminosity range, the one with low fractional luminosities consists of objects between $0.6 L_{\odot}$ and $58 L_{\odot}$ while the other one with high fractional luminosity targets covers a range between $1.1 L_{\odot}$ and $31 L_{\odot}$. Considering the subsample of high fractional luminosity discs, the grain size s_{\min} is roughly consistent with a constant value of $\sim 5 \mu\text{m}$ and shows only a weak, decreasing correlation with the stellar luminosity which is not statistically significant ($r_{\text{Pearson}} = -0.21$ and $r_{\text{Spearman}} = -0.24$). The low fractional luminosity subsample shows as well a not significant correlation between the minimum grain size and the stellar luminosity ($r_{\text{Pearson}} = 0.27$ and $r_{\text{Spearman}} = 0.20$). Applying the t-score, it turns out that $t = 3.05$ and hence, $p = 0.005$. This means, that the subsamples are statistically different from each other. In case of the s_{\min}/s_{blow} ratio $t = 2.74$ and $p = 0.011$ which only shows marginally differences. Here, the slope is stronger for high fractional luminosity discs ($r_{\text{Pearson}} = -0.93$ and $r_{\text{Spearman}} = -0.96$), but both subsamples show a strong correlation (low fractional luminosity: $r_{\text{Pearson}} = -0.80$ and $r_{\text{Spearman}} = -0.72$). Obviously, the scatter is smaller for the high fractional luminosity subsample which is also reported in Section 6.6. One explanation for the differences between high and low fractional luminosity discs is that with a higher f_d the infrared excess is more pronounced and thus the SED fit is more reliable and less uncertain. A confirmation for this assumption is that the scatter of data for high fractional luminosity discs around the regression line is smaller (the correlation between the grain size ratio or the grain size and the stellar luminosity is stronger) than for low fractional luminosity objects. The uncertainties of the trend line parameters in Figure 7.4 show that. While it is 0.10 for the low fractional luminosity sample it is only 0.06 for the high- f_d one. Besides this more technical explanation there is also a physical possibility

for differences between the two subsamples. It might be that high and low fractional luminosity discs differ in one or another respect. If this is the case, than there should be systematic differences in subsamples of other key parameters (e.g., disc radius or system's age) as well.

7.3.3 Small vs. large discs and young vs. old discs

The differences in the two subsamples of high and low fractional luminosity discs might be explained due to systematic differences in the disc radius or the stellar system's age (e.g., Moór et al., 2006). For example, debris discs are expected to loose dust mass and therefore fractional luminosity during the collisional evolution. In this process planetesimals are ground to dust and particles of sub-blowout size are produced and then expelled from the debris disc system due to stellar radiation pressure (Wyatt et al., 2007a; Löhne et al., 2008). Considering the minimum and maximum fractional luminosity the disc radius is expected to be larger for high fractional luminosity discs than for low fractional luminosity ones (see Figure 2.10).

Considering discs of a fractional luminosity $f_d < 6.50 \times 10^{-5}$ the average disc radius lies at (110 ± 48) AU, while for discs with $f_d \geq 6.50 \times 10^{-5}$ it is (170 ± 51) AU. Hence, the radii of low fractional luminosity discs seem to be smaller. The average ages of both subsamples are (547 ± 666) Myr and (519 ± 685) Myr respectively, which leads to the impression that low fractional luminosity discs might be slightly older (ignoring the large uncertainties). However, the standard deviations in both cases are large and a statistical test is necessary in order to get reliable conclusions. The null hypothesis for the following AD-test (see Chapter 2.3) is given by the disc radii and the ages being indistinguishable for both subsamples. In Chapter 5.3.3, we inferred the uncertainty of the disc radii derived to be 8%, while we assume an uncertainty of 25% in the age of the host stars estimated by $25\% \times \log_{10}(T_{\text{age}}/\text{Myr})$. The test parameters for the AD-test are given by Equations (2.46) and (2.47), where we use $n_1 = 15$, $n_2 = 16$ as subsample sizes and $k = 2$ as number of the subsamples. In that case, the critical value for the rejection of the null hypothesis is $t_1 = 3.75$ at a significance level of $\alpha = 0.01$ (Scholz and Stephens, 1987). The result for the disc radii is a value of $T = 5.28 \pm 1.05$ which is larger than the critical value. On the other hand, the AD-test for the ages led to a value of $T = -0.20 \pm 0.77$. Therefore, we can say that the radii of low and high fractional luminosity discs may be statistically distinguishable, whereas the ages of the discs are clearly indistinguishable.

In addition we divided the sample into subsamples of small ($R_{\text{disc}} \leq 129$ AU) and large discs ($R_{\text{disc}} \geq 129$ AU) as well as into young ($T_{\text{age}} < 276$ Myr) and old discs ($T_{\text{age}} \geq 276$ Myr). For both we used the median as separation value. The resulting statistical parameters of the two-sample tests are given in Table 7.1. As listed there, the subsamples of disc radii and stellar age are indistinguishable from each other, since the p -probabilities with 0.20 (disc radii) and 0.29 (stellar age) are much larger than the significance level of 0.01. Hence, the marginal differences between the discs of high and low fractional luminosity seem to originate more in the quality of the fits than in a physical reason.

7.3.4 Faint vs. bright discs

In an additional attempt, we chose the absolute integrated flux from the disc and that flux divided by the disc extent as splitting parameter, P , in order to investigate possible systematic errors stemming from the images. An example for such a systematic would be, that discs with a high absolute flux might be larger, since a larger fraction of the disc would be visible above the noise. We used the absolute *integrated* brightness at $100\mu\text{m}$ and the absolute *surface* brightness to generate the two subsamples. The results can be seen in Figure 7.6. Here, the objects HD 9672 (49 Cet), HD 172167 (Vega) and HD 216956 (Fomalhaut) are excluded, since they have no *Herschel*-measured fluxes at $100\mu\text{m}$. Therefore, the size of the subsamples is $n_1 = n_2 = 14$. The two subsamples of both, integrated and

Figure 7.5: Same as Figures 7.3 and 7.4, but for the two subsamples based on the disc radius (left) and the stellar age (right). Left: blue line and squares: $R_{\text{disc}} \leq 129$ AU; red line and circles: $R_{\text{disc}} \geq 129$ AU; right: blue line and squares: systems younger than 276 Myr; red line and circles: systems older than 276 Myr; both panels: black line: the entire sample.

Figure 7.6: Same as Figures 7.3–7.5, but for the two subsamples based on disc’s absolute integrated brightness (left) and absolute surface brightness (right). Blue line and squares: faint discs; red line and circles: bright discs; black line: the entire sample.

surface brightness include a wide range of stellar luminosities. The regression lines for the surface brightness show no significant differences which is confirmed by a p -probability of 0.69. On the other hand, there are variations for the integrated brightness ($p = 0.006$, see Table 7.1). Comparing these new results with the result of the chapter before, it seems that the differences in the regression lines are caused by the quality of the SED fit and not by a physical effect. Indeed, Figure 7.7 shows that there is a correlation between the integrated brightness and the fractional luminosity. Since there are no differences in the subsamples divided by surface brightness, systematic uncertainties caused by the images seem not to be the reason for the differences in the subsamples of high and low fractional luminosity.

7.3.5 Marginally-resolved vs well-resolved discs

Another possible explanation for the different trend lines might be the uncertainties of the measured disc radii. We used the discs’ FWHM at 100 μm and compared it to the width of the *Herschel*/PACS point-spread function (PSF) at the same wavelength (6.7''). The sample was splitted into well resolved discs with an $\text{FWHM} \geq 10.6''$ (i.e., $\text{FWHM} \geq 1.6\text{PSF}$) and marginally resolved discs with an $\text{FWHM} < 10.6''$ (i.e., $\text{FWHM} < 1.6\text{PSF}$). The results are shown in Figure 7.8. Most of the marginally

Figure 7.7: Integrated brightness at 100 μm as a function of fractional luminosity. Excluded are 49 Cet, Fomalhaut and Vega, since they do not have integrated brightnesses at 100 μm . The straight solid line shows the best log-log-fit through the symbols.

Figure 7.8: Same as Figures 7.3–7.6, but for the two subsamples based on disc’s FWHM at 100 μm . Blue line and squares: marginally resolved discs; red line and circles: well-resolved discs; black line: the entire sample.

resolved discs of the sample can be found around high stellar luminosity stars, while the majority of the well resolved discs have lower stellar luminosities. This is in agreement with Figure 5.3. The regression lines of both subsamples reveal no significant differences with $p = 0.64$ (see Table 7.1).

All in all, we can say that the $s_{\text{min}}/s_{\text{slow}}$ trend with the stellar luminosity persists, although discs with high and low fractional luminosity or high and low integrated brightness reveal small differences in the steepness of the slope. Therefore, a statistical effect causing this trend can be excluded as well and now, physical processes can be investigated.

7.4 The role of the surface energy constraint

The analysis of the $s_{\text{min}}/s_{\text{slow}}$ trend with stellar luminosity led to the assumption that this correlation does not have a statistical or technical cause. Hence, physical processes have to be investigated in order to explain it.

The model without radiation pressure

The first idea is that it is not possible to produce smaller collisional fragments around low-luminosity stars. The reason was given by Krijt and Kama (2014), who stated that the minimum size of collisional fragments should be connected to the impact energy available. They showed the s_{\min}/s_{blow} ratio to be describable by

$$x \equiv \frac{s_{\min}}{s_{\text{blow}}} = 48A \left(\frac{0.01}{f} \right)^2, \quad (7.3)$$

where

$$A \equiv \left(\frac{R_{\text{disc}}}{100 \text{ AU}} \right) \left(\frac{L_{\odot}}{L} \right) \left(\frac{0.01}{\eta} \right) \left(\frac{\gamma}{100 \text{ erg cm}^{-2}} \right), \quad (7.4)$$

γ the surface energy per unit surface of the material and η the fraction of kinetic energy which is used to create the new surface. The parameter f is given by

$$f = \frac{v_{\text{rel}}}{v_{\text{K}}} = v_{\text{rel}} / \sqrt{\frac{GM_{\text{star}}}{R_{\text{disc}}}}, \quad (7.5)$$

with v_{K} being the Keplerian orbital velocity and v_{rel} the relative velocity of the colliders. Krijt and Kama (2014) set this velocity ratio equal to the average eccentricity of the dust parent planetesimals, $\langle e \rangle$, which can also be called the dynamical excitation.

Figure 7.9: The s_{\min}/s_{blow} ratio as a function of stellar luminosity, assuming pure astrosilicate grains. Symbols with error bars: discs of our sample with $f_{\text{d}} \geq 6.50 \times 10^{-5}$. Gray-shaded area: region of blowout grains. Dashed lines: original model by Krijt and Kama (2014), Equation (7.3). Grains below the dashed lines are excluded by these models, because they should not be produced. Different line colours correspond to different degrees of dynamical excitations: $\langle e \rangle = 0.01$ (blue), $\langle e \rangle = 0.02$ (green), $\langle e \rangle = 0.03$ (yellow), $\langle e \rangle = 0.05$ (orange); $\gamma = 100 \text{ erg cm}^{-2}$.

In Figure 7.9 the s_{\min}/s_{blow} ratio as function of stellar luminosity is presented for the subsample of 16 discs of high fractional luminosities. We chose this subsample since the fit results may be more reliable than for the whole sample, which was explained in Section 7.3. Furthermore, the grain size correlation was found to be stronger for this subsample and hence it is easier to compare the models. Using the Krijt-and-Kama model (Equation (7.3)) and comparing it to the $s_{\min}/s_{\text{blow}}-L$ correlation found for the sample of resolved discs, we got the following results depicted in Figure 7.9. The parameter values were assumed to be $\eta = 0.01$ and $\gamma = 100 \text{ erg cm}^{-2}$, but they are highly uncertain.

Particles with a size ratio below the dashed lines cannot be produced in a collision, since there would be not enough impact energy to build their surface. On the other hand, smaller grains can be created if their eccentricity is larger. Referring to the sample of resolved discs, the forbidden areas below $\langle e \rangle \approx 0.02\text{--}0.03$ and below the blowout limit match the region where no data points can be found (except for HD 182681 which lies below the blowout limit).

The model including radiation pressure

Due to the radiation pressure the eccentricities of dust grain orbits are higher than those of their parent planetesimals and hence there is a possibility to improve the above mentioned model, as noted by Krijt and Kama (2014). The parameter f is connected to the average eccentricity of solids, which are the “immediate parents” of the smallest collisional fragments. It is assumed that these particles have a radius of bs_{\min} with $b > 1$ being a numerical factor. They have the same dynamical excitation as the planetesimals from which they originate, but the radiation pressure causes an increase in their eccentricities (see Chapter 2.2.2). Now, the parameter f can be adopted as

$$f \approx \sqrt{\langle e \rangle^2 + \left(\frac{\beta}{1 - \beta} \right)^2}, \quad (7.6)$$

with β given by Equation (2.16) (e.g., Lissauer and Stewart, 1993). Since Equations (7.3)–(7.4) assume $Q_{\text{pr}} = 1$, this relation is used as well for the sake of simplicity and allows to set $\beta = 1/(2bx)$. With this, Equation (7.3) can be written as

$$x = 48A \left(\frac{0.01}{\langle e \rangle} \right)^2 \left[1 + \frac{1}{\langle e \rangle^2 (2bx - 1)^2} \right]^{-1} \quad (7.7)$$

Depending on b the discriminant of this cubic function is smaller than zero for $\langle e \rangle$ smaller than a certain value (e.g., for $b = 10$, the dynamical excitation must be $\langle e \rangle \lesssim 0.04$) and thus three real solutions for s_{\min}/s_{blow} exist in this case. For larger $\langle e \rangle$ the discriminant is larger than zero and so only one real solution can be obtained while the other two are imaginary. Considering a discriminant smaller than zero, the largest root of the cubic function leads to the s_{\min}/s_{blow} of interest, while for $b \rightarrow \infty$ the simplified equation of Krijt and Kama (2014) can be obtained. The two other roots of Equations (7.7) have a physical meaning as well. If the eccentricities of the parent particles are sufficiently high due to radiation pressure, the fragments with an s_{\min}/s_{blow} ratio between these roots can be created. A limiting case explaining this is $\langle e \rangle \rightarrow 0$. Here, the cubic function can be simplified to a quadratic one with

$$x = 4.8 \times 10^{-3} A (2bx - 1)^2. \quad (7.8)$$

Now, the particles with s_{\min}/s_{blow} between the two roots of this equation have large radiation pressure-induced eccentricities and therefore, the impact energies are high enough to create these fragments. Considering the parameter ranges used in this work, the two roots are smaller than unity, which means that the minimum grain size, s_{\min} is smaller than the blowout limit, s_{blow} and thus, they do not play a physical role in this case. In Figure 7.10 the forbidden areas of the improved model including radiation pressure (using Equation (7.7)) are shown in comparison to the model excluding radiation pressure (using Equation (7.3)). Both models use the same eccentricities $\langle e \rangle$, while the factor b was set to 10. This means that the collisional targets are on average ten times larger than the resulting fragments (See Krivov et al., 2005, for justification of this choice and additional references.).

Comparing the s_{\min}/s_{blow} trend of the data set with both, the simplified and the improved model the latter one seems to reproduce the data not as well as the original one. Since some parameters,

Figure 7.10: The s_{\min}/s_{blow} ratio as a function of stellar luminosity, assuming pure astrosilicate grains. Symbols with error bars: discs of our sample with $f_d \geq 6.50 \times 10^{-5}$. Gray-shaded area: region of blowout grains. Dashed lines: original model by Krijt and Kama (2014), Eq. (7.3). Filled areas: improved model, Eq. (7.7). Grains below the dashed lines and those in filled areas are excluded by these models, because they should not be produced. Different line and filling colours correspond to different degrees of the dynamical excitation, $\langle e \rangle$. Left: $\gamma = 100 \text{ erg cm}^{-2}$, symbols represent the full sample; right: $\gamma = 2000 \text{ erg cm}^{-2}$.

like γ or η , are uncertain a better adaption to the data can be generated by varying these parameters in the given equations. This was done in the right panel of Figure 7.10, where γ was increased from 100 erg/cm^2 to 2000 erg/cm^2 . The former value is realistic for icy materials (Wada et al., 2007; Gundlach et al., 2011) whereas the latter one is more appropriate for e.g., silicon (Gilman, 1960). As well, a lower energy fraction might be used. The result is a good match at higher eccentricities, e.g., at $\langle e \rangle \approx 0.10$ the area excluded by the improved model could describe the decrease of s_{\min}/s_{blow} .

However, Thebault (2016) investigated the surface energy constraint in more detail by incorporating it into a statistical code for collisional evolution of debris discs. Here, not only equal-sized colliders (as in Krijt and Kama (2014)) were assumed, but a distribution (s_i, s_j) of them. He found that for all pairs of colliders the energy constraint can be observed, especially around low-mass stars or in discs with low $\langle e \rangle$ it has a significant effect. In general this confirms the results found in Pawellek and Krivov (2015) and in the previous sections of this work, but there are limitations as well. For example, the pairs of colliders for which the surface energy constraint has the largest effect are not the same pairs which produce the most of the dust. Thus, the global influence of the surface energy constraint is relatively small. Only for discs around solar-type stars which have a high dynamical excitation the constraint has a visible effect on the size distribution of dust particles. It was expected that in discs with $\langle e \rangle = 0.01$ the effect should be the strongest, but contrarily no visible effect on the size distribution is detectable here. Thebault (2016) concluded that in such discs another mechanism dominates the size distribution at small sizes, namely the imbalance of a small dust production and destruction rate (Thébault and Wu, 2008) in dynamically cold discs. Mentioning the degree of excitation of debris discs in connection to the surface energy constraint the influence of the stirring level on the grain size ratio - stellar luminosity trend will be the next point of investigation.

7.5 The role of the stirring level

In this section we will have a closer look on the balance between dust production and destruction rate of small particles. It is related to the microphysical effect of the surface energy constraint explained

in the last section, but it is controlled by the level of stirring of the larger, macrophysical bodies.

7.5.1 Idea

The grain size distribution depends on the degree of dynamical excitation of the dust producing planetesimals, $\langle e \rangle$ (Thébault and Wu, 2008). To explain this idea, we assume planetesimals with a low dynamical excitation, which is still sufficiently high for collisions to be mostly destructive. In this case the collision velocities between large grains not influenced by stellar radiation pressure are low and therefore, the *production* rate of small grains is decreased compared to the production rate in systems with a higher dynamical excitation.

On the other hand, the *destruction* rate of the small particles is related to their eccentricities and these are set by stellar radiation pressure. Hence, it is independent of the dynamical excitation of the parent bodies and stays the same. Considering the low dynamical excitation, a smaller number of particles is produced, but the same number is destroyed and therefore, a dearth of small particles should be the result leading to a shift of the maximum of the size distribution and the s_{\min}/s_{blow} ratio to larger values. This can be seen in Figure 7.11 considering the right maximum of the distribution. The dominant grain size (s_{\min}) should be the peak of the size distribution. Particles of this size

Figure 7.11: Geometrical cross section as a function of grain size for different dynamical excitations. The right maximum shifts towards larger values for lower dynamical excitations. The maximum for the smallest grains on the left side is caused by a lack of even smaller particles which could destroy their parent bodies. From Thébault and Wu (2008).

have inherited the eccentricity, $\langle e \rangle$, of their parent planetesimals which is the same as the radiation pressure-induced eccentricity, $\beta/(1-\beta)$, here. Assuming $Q_{\text{pr}} = 1$ again, $\beta \approx 0.5(s_{\text{blow}}/s_{\min})$ and thus,

$$\frac{s_{\min}}{s_{\text{blow}}} \approx \frac{\langle e \rangle^{-1} + 1}{2} \quad (7.9)$$

can be taken as rough estimate provable by collisional simulations. Pawellek and Krivov (2015) used the collisional code ACE (Krivov et al., 2013) treating the collisional and radiation pressure forces in a more realistic way by including cratering collisions, rebounds and sticking. Furthermore, they considered low-luminosity stars besides A-stars already treated in Thébault and Wu (2008).

7.5.2 ACE runs

In order to test the effect in more detail, several ACE runs were necessary. Following Pawellek and Krivov (2015) two different central stars (A2V with $17.4 L_{\odot}$ and G2V with $1 L_{\odot}$) and two different

stirring levels (average planetesimals’ eccentricity of 0.1 and 0.01, average inclination according to the energy equipartition) were investigated. The code considered stellar gravity, direct radiation pressure and Poynting-Robertson drag besides the above mentioned possible collisional outcomes (disruptive, cratering, rebounding, and sticking collisions). The initial disc mass was assumed to be $30 M_{\oplus}$ (in the bodies of up to 100 km radius), leading to typical fractional luminosities of the dust in the sample of resolved debris discs, while the disc radius was taken as (100 ± 10) AU. The other standard assumptions for the model runs are compact astrosilicate as dust composition (Draine, 2003a) and a critical fragmentation energy from Benz and Asphaug (1999). The collisional evolution run was stopped at a quasi-steady state defined in Löhne et al. (2008).

7.5.3 Results

Size distribution

Figure 7.12 depicts the resulting size distribution from the described ACE runs. Comparing them with Figure 7.11 we can say that both diagrams show similar results. The maximum of the size distribution is shifted to higher values for lower dynamical excitations, $\langle e \rangle$. Furthermore, it is obvious that the size distribution generated with ACE has significant differences comparing to a power law distribution with a sharp cutoff size (see Figure 2.9).

Figure 7.12: Simulated size distributions in the fiducial discs around A2-stars (thick lines) and G2-stars (thin lines) with higher (red) and lower (blue) level of stirring. Plotted is the size distribution in the parent ring, assumed to be located at 100 AU. Vertical dashed lines mark the radiation pressure blowout limit of A2-stars (thick) and G2-stars (thin). Note that two blowout values exist for the G2-stars. The grains in unbound orbits are those between these two.

Beginning with the distribution for the A-star, a “plateau” can be seen between $s_{\text{blow}} = 3.0 \mu\text{m}$ and a shallow maximum at $12 \mu\text{m}$ (for $\langle e \rangle = 0.10$). This maximum increases towards $50 \mu\text{m}$ in case of a dynamically cold disc (i.e. for $\langle e \rangle = 0.01$). There are different-sized grains in the given size area contributing almost equally to the dust cross section. Thus, a geometric mean value between the lower and higher end of the plateau is taken as the minimum or dominant grain size, s_{min} .

The disc around the G2-star has a blowout size of $s_{\text{blow}} = 0.46 \mu\text{m}$ and a size distribution maximum at $2.6 \mu\text{m}$ for $\langle e \rangle = 0.10$ or $10 \mu\text{m}$ for $\langle e \rangle = 0.01$, respectively. Here, a second blowout limit does exist as well, meaning that particles smaller than $\lesssim 0.1 \mu\text{m}$ are staying in bound orbits and are contributing

a large fraction to the dust’s total cross section. The absorption efficiency, Q_{abs} , of these “sub-blowout grains” is much lower compared to the larger bound particles (see Figure 2.3) and hence they only play a minor role in the observed emission, which lies at the order of $\sim 10\%$ at all wavelengths. Therefore, the grains do not have a direct relevance to the discussed lower cutoff size of the size distribution, but they do affect the distribution, since they are able to collide with the grains just above the upper blowout limit and thus “erode” these particles.

Grain size ratio

The next step after analysing the size distribution is the investigation of the resulting grain size ratio - stellar luminosity trend depicted in Figure 7.13. Here, the results from the sample of resolved discs are compared to the ACE runs. The expectation was that $s_{\text{min}}/s_{\text{blow}}$ increases with decreasing dynamical

Figure 7.13: Symbols with error bars represent the discs of our sample (assuming pure astrosilicate) and the thick black line is the best-fit through these data. Asterisks mark approximate values of $s_{\text{min}}/s_{\text{blow}}$ extracted from ACE simulations, as described in the text. The pairs of asterisks corresponding to the same dynamical excitation, $\langle e \rangle$, are connected with dashed lines for illustrative purposes.

excitation, $\langle e \rangle$, and this is confirmed for both stars. It is as well roughly consistent with Equation (7.9). Another interesting result is given by the fact that the lines of constant dynamical excitation are tilted and thus s_{min} becomes closer to s_{blow} for high luminosity stars even if the dynamical excitation stays constant. This effect was not expected before the modelling and it was reported in Pawellek and Krivov (2015) for the first time. Furthermore, it mimics the $s_{\text{min}}/s_{\text{blow}} - L$ trend found for the sample of resolved discs. Comparing the $s_{\text{min}}/s_{\text{blow}} - L$ trend with the lines of equal dynamical excitation it is obvious that the trend does not confirm an assumption of constant $\langle e \rangle$ for the whole stellar luminosity range. In fact, a dynamical excitation between 0.01 and 0.1 for G-stars and $\gtrsim 0.1$ for A-stars seems to be the best approximation of the data. Looking at the results of detailed collisional modelling of several individual objects the increase of dynamical excitation with increasing stellar luminosity is supported by Löhne et al. (2012) and Schüppler et al. (2014) who analysed a G0V-star HD 207129 and a K2V-star HIP 17439 respectively and found $\langle e \rangle$ being at the order of a few per cent. On the other hand the modellings of the A5V-star HR8799 (Matthews et al., 2014a) and the A0V-star Vega

(Müller et al., 2010) lead to a value of $\langle e \rangle \sim 0.1$. In case of HR 8799 the higher dynamical excitation is expected since a substantial outer halo of small particles is present. However, the increase of dynamical excitation with increasing stellar luminosity is a general statistical trend. Indeed, there is a scatter for individual systems and as well there might be discs which do not follow this trend at all.

Another interesting aspect is the “self-regulation” of the $s_{\min}/s_{\text{blow}}(L)$ dependence which can be explained as follows. The dynamical excitation of discs around more luminous stars is assumed to be stronger and therefore, such discs should possess more pronounced halos. These halos would lead to an overestimation of the disc radii of early-type stars since they were inferred from the images. As a consequence the dust grain sizes would be underestimated (Pawellek et al., 2014). The correction of this effect would lead to a raise of the data points on the right side of Figure 7.13 and thus to a flattening of the $s_{\min}/s_{\text{blow}}(L)$ trend. In case of these discs the level of dynamical excitation would decrease. If $\langle e \rangle$ is lower, the halos are assumed to be weaker which results in a drop down of the data points of more luminous stars in Figure 7.13. The s_{\min}/s_{blow} ratio is smaller, the $s_{\min}/s_{\text{blow}}(L)$ trend shows a steeper decrease and all is reset to the starting conditions. So this trend seems to be robust considering the uncertainties of the measured disc radii.

It should be also remarked that both, the stirring models and the surface energy models mentioned in section 7.4 depend on each other. Assuming that the stirring level is correlated with the stellar luminosity as proposed here, the surface energy constraint described in section 7.4 will be affected as well, which results in a change of the filled areas depicted in Figure 7.9. A combination of both effects to a single model would be a good way in future works, e.g., the surface energy constraint could be implemented into the above mentioned collisional code ACE, since the collisional simulations shown in this section did not include it.

Figure 7.14: Mass of the protoplanetary disc as function of stellar mass. From Williams and Cieza (2011).

The question arises whether the correlation between the dynamical excitation and the stellar luminosity can be expected. For instance, Williams and Cieza (2011) investigated protoplanetary discs which are the progenitors of debris discs. They showed that the submillimeter dust masses in such discs are correlated with the masses of their central stars (see Figure 7.14). So there is a possibility that discs around more massive, high-luminosity stars possess a larger mass and therefore could form a larger number of large planetesimals. In debris discs these large planetesimals could act as stirrers (the so-called “self-stirring scenario”, e.g., Wyatt, 2008; Kennedy and Wyatt, 2010), which is supported by simulations of planetesimal accretion (e.g., Kenyon and Bromley, 2008). The protoplanetary discs may not only be more successful in the formation of large planetesimals but also in building more massive giant planets. In the past, these planets could have been subject to scattering or vigorous migra-

tion resulting in a higher dynamical excitation of debris discs (the “planetary stirring scenario”, e.g., Mustill and Wyatt, 2009). Supporting results for this theory come from both observational (e.g., Johnson et al., 2010; Reffert et al., 2015) and theoretical investigations (e.g., Ida and Lin, 2005; Kennedy and Kenyon, 2008; Alibert et al., 2011; Mordasini et al., 2012), who concluded that more massive stars possess giant planets more frequently and that the typical planet mass is larger. Nevertheless, the above mentioned possibilities have to be tested further in order to validate them.

8 Application to radii of unresolved discs

In the last chapter we analysed the grain size ratio - stellar luminosity trend and tried to explain its cause by investigating different technical and physical effects. Now we will concentrate on another trend found and described briefly in section 6.2.3, the ratio of the disc radius to the blackbody radius, Γ , as a function of stellar luminosity. It was shown in Figure 7.1b for the whole sample of 39 resolved debris discs and different dust compositions. Its existence allows us to estimate the radii of debris discs which could not be spatially resolved yet. Referring to section 7.3, we will analyse possible outliers at first in order to investigate the influence of individual objects. Then, we will give a recipe for the estimation of the “true” disc radius of unresolved discs followed by an application to resolved discs not included in the sample used in this work.

8.1 Outliers

8.1.1 Low-luminosity stars

As mentioned in sections 6.2.2 and 6.3, the radii ratios for stars with a stellar luminosity smaller than $1 L_{\odot}$ are smaller than expected from the trend line, which is partially explainable by the absorption properties of the dust grains. Thus, the correlation found between the radius ratio and the stellar luminosity is not the same for low-luminosity stars as for stars with higher stellar luminosities. In

Figure 8.1: Radius ratio as function of stellar luminosity. Black filled squares with error bars show the 39 data points. The black solid line shows the best log-log fit through the symbols. The red solid line shows the best log-log fit for objects with $L > 1 L_{\odot}$. Pure astrosilicate was assumed.

Figure 8.1 the influence of the low-luminosity stars on the trend line is depicted. While the slope

for the whole sample is -0.33 ± 0.05 using pure astrosilicate, it is changed to -0.38 ± 0.06 when all stars with $L < 1 L_{\odot}$ are excluded. Taking the uncertainties of the fit into account both lines show a similar trend. The small influence of the low-luminosity stars on the trend can be explained by larger uncertainties of their radius ratio. In order to get a reliable estimate of the radii of unresolved discs we will exclude all stars with $L < 1 L_{\odot}$. Hence, 31 objects remain in the sample used for the radius estimate.

8.1.2 Other outliers

After excluding the low-luminosity stars from the sample we investigate the influence of the remaining stars on the trend. Therefore, we will use the same method as described in section 7.2. Figure 8.2 shows the result of this analysis. The influence of individual objects is relatively small. The strongest

Figure 8.2: Identification of outliers in $s_{\min}/s_{\text{slow}}(L)$ for pure astrosilicate. Left: the factors A and slopes B of the trend lines in the form $A (L/L_{\odot})^B$, calculated by excluding from the sample one data point at a time. Error bars are uncertainties in A and B returned by the fitting. The “cross-hairs” depict the best fit through the whole sample. The strongest outliers are shown in colour: red is HD 104860, light blue is HD 10647, orange is η Crv, green is Vega, and blue is β Tri. Right: size ratio versus stellar luminosity for pure astrosilicate with and without outliers. The colour coding is the same as on the left. The black line gives the trend line for the entire sample. The line of a certain colour is the best fit without the object of the same colour. The removal of HD 10647 or η Crv lead to similar regression lines as well as the removal of Vega or β Tri. Therefore, only the result for the removal of η Crv and Vega are shown.

outliers are HD 104860, Vega, and β Tri. Interestingly, η Crv is an obvious outlier, but causes no significant change in the trend line. This is a slightly different result than reported in Pawellek and Krivov (2015) and can be explained by an improvement of the error analysis of the SED fit process. While in Pawellek and Krivov (2015) η Crv had a small uncertainty compared to the other discs the new calculation led to smaller uncertainties for most of the data points making the trend more robust against the influence of individual systems. This is supported by Figure 8.2 where the slope values of the different trend lines in the right panel show similar results within the uncertainties. In order to make the trend as robust as possible we will exclude all five outliers, namely q^1 Eri, HD 104860, η Crv, Vega and β Tri, which reduces the sample size to 27.

8.2 Influence of dust compositions

We assume the best-fit relation between Γ and the stellar luminosity as

$$\Gamma = A (L/L_{\odot})^B. \quad (8.1)$$

The values of the power law coefficients A and B are given in Table 8.1 for the sample of 27 objects. The trend lines for all dust compositions show a similar slope taking the uncertainties into account. While in Pawellek and Krivov (2015) astrosilicate showed the steepest trend with $A = 8.26 \pm 1.27$ and $B = -0.55 \pm 0.04$ it changed to $A = 6.49 \pm 0.86$ and $B = -0.37 \pm 0.05$ in this work. Reasons are the improvement of the error calculation process during the SED fitting and the improvement of the derivation of the true disc radius compared to Pawellek et al. (2014). Now, the composition of astrosilicate and ice possesses the steepest trend with $A = 8.38 \pm 1.20$ and $B = -0.44 \pm 0.05$. Compared

Table 8.1: Power-law coefficients for the Γ ratio

Dust composition	A	B
50% astrosilicate + 50% vacuum	6.93 ± 0.84	-0.40 ± 0.04
50% astrosilicate + 50% ice	8.38 ± 1.20	-0.44 ± 0.05
100% astrosilicate	6.49 ± 0.86	-0.37 ± 0.05
50% astrosilicate + 50% carbon	6.15 ± 0.76	-0.36 ± 0.05
100% carbon	6.43 ± 0.71	-0.40 ± 0.04

to Pawellek and Krivov (2015), where the standard deviation of the slope was 0.07, the trend lines calculated in this work are not as much influenced by the different dust compositions. The standard deviation of the slope is now 0.03.

After analysing the radius ratio trend with increasing stellar luminosity we are now going to use the results described above in order to estimate the disc radii of unresolved debris discs.

8.3 Estimation of unresolved disc radii

8.3.1 Calculation recipe

The disc radius gives information about formation processes of planetesimals and planets and thus, it is an important parameter for modelling debris discs. Unfortunately, most of the known debris discs are unresolved and therefore, it is useful to have a possibility to estimate the disc radius of such discs. The correlation between the ratio of true to blackbody radius and stellar luminosity gives us a good chance to do that.

We will use the following steps in order to estimate the disc radius. At first it is necessary to derive the dust temperature T_d of the disc. This can be done by a SED fit of the disc with one or another disc model, for instance, the modified blackbody radiation model (Backman and Paresce, 1993). Another way is to estimate the temperature from the wavelength λ_{\max} of the maximum excess emission by $T_d = 5100 \text{ K} (1 \mu\text{m}/\lambda_{\max})$. After deriving the dust temperature it is possible to calculate the blackbody radius of the disc with help of the bolometric luminosity and

$$R_{\text{BB}} = \left(\frac{278 \text{ K}}{T_d} \right)^2 \left(\frac{L}{L_{\odot}} \right)^{1/2} \text{ AU}. \quad (8.2)$$

Equation (8.1) was used in the last section to describe the correlation between the radius ratio and the stellar luminosity. Now, it can be used to compute the “true” disc radius by multiplying Γ by R_{BB} with help of the coefficients A and B given in Table 8.1. Since the coefficients depend on the dust composition, the most appropriate should be chosen. The SED fit can give some hints in that case if several dust compositions are tested. The composition delivering the smallest χ^2 value is often assumed as the best choice.

The described recipe for the radius estimation has to be tested in order to check the reliability of it. Therefore, we will use resolved discs which were not included in the sample of this work to derive Γ . The radii of these discs are known and so we have a possibility to compare the radii reported in the literature and measured from the resolved images with the calculated ones.

8.3.2 Application to resolved discs

We arbitrarily chose three discs resolved in scattered light in order to check the reliability of the radius estimation. Since their radii were not inferred from the measurements of the *Herschel*/PACS instrument these discs are the most suitable objects to test the method described above. The discs are around the G2V star HD 107146 (taking the data from Ardila et al., 2004; Williams et al., 2004; Ertel et al., 2011), the F5V star HD 181327 (Schneider et al., 2006; Lebreton et al., 2012), and the A7 star HD 32297 (Kalas, 2005; Schneider et al., 2005; Donaldson et al., 2013). For all discs we calculated the “true” disc radius for all five dust compositions used in this work. The results are listed in Table 8.2. The estimate of the true disc radius gives reasonable results for all three discs. While the recipe leads

Table 8.2: Resolved discs used to test the $\Gamma(L)$ relation.

HD number	L/L_{\odot}	$T_{\text{d}}[K]$	$R_{\text{BB}}[\text{AU}]$	Γ_{pred}	$R_{\text{pred}}[\text{AU}]$	$R_{\text{true}}[\text{AU}]$
107146	1.1	51	31	6.7 (astrosil+vacuum)	208 (astrosil+vacuum)	130
				8.0 (astrosil+ice)	248 (astrosil+ice)	
				6.3 (astrosil)	195 (astrosil)	
				5.9 (astrosil+carbon)	183 (astrosil+carbon)	
				6.2 (carbon)	192 (carbon)	
181327	3.3	73	26	4.3 (astrosil+vacuum)	112 (astrosil+vacuum)	89
				5.0 (astrosil+ice)	130 (astrosil+ice)	
				4.2 (astrosil)	109 (astrosil)	
				4.0 (astrosil+carbon)	104 (astrosil+carbon)	
				4.0 (carbon)	104 (carbon)	
32297	5.3	83	26	3.6 (astrosil+vacuum)	94 (astrosil+vacuum)	110
				4.0 (astrosil+ice)	104 (astrosil+ice)	
				3.5 (astrosil)	91 (astrosil)	
				3.4 (astrosil+carbon)	88 (astrosil+carbon)	
				3.3 (carbon)	86 (carbon)	

to a large overestimate in case of the solar-type star, it delivers a value close to the true one for the A-star. The low-luminosity stars show a different behaviour in the Γ -trend due to the absorption properties of their dust. Thus, the radius estimate is not appropriate for these stars. Since HD 107146 has a stellar luminosity close to the cut-off luminosity of $1 L_{\odot}$ for this method the estimate is not as good here as for the other two stars with higher stellar luminosities.

At this point it seems that the dust composition of astrosilicate and ice would be a poor choice for the estimation of the true disc radius. But here, the object HD 95086 leads to the large regression parameters A and B . If we remove this data point from the sample, the values of the regression change

to $A = 7.00 \pm 0.67$ and $B = -0.39 \pm 0.03$. Using them instead of the values given in Table 8.1 the disc radii of the three resolved discs are 209 AU for HD 107146, 114 AU for HD 181327 and 95 AU for HD 32297. These results are more comparable to the estimation by the composition of astrosilicate and vacuum. These two mixtures are often used in the literature (e.g, Lebreton et al., 2012; Donaldson et al., 2013) instead of pure astrosilicate, but since the derived disc radii for all dust compositions are close to each other the choice of the mixture seems to play a minor role here. On the other hand, the sample size from which the correlation coefficients were calculated is quite small. Therefore, it would be necessary to enlarge the sample and to check whether conclusions about the dust composition are possible.

Figure 8.3: The predicted ratio of the true disc radius to the blackbody radius, Γ , for pure astrosilicate. The solid line is the best-fit relation, Eq. (8.1). The areas filled with dark-, medium-, and light-grey are 1σ -, 2σ -, and 3σ -confidence areas for that relation, respectively. The symbols show the actual Γ values (i.e., observed versus blackbody radius) for three selected test discs. Unlabeled small symbols with error bars are fitting results for the discs in our sample, for the same dust composition. These are the same as blue symbols in Fig. 7.1b. Left: the sample excluding stars with $L < 1L_{\odot}$. Right: five outliers (HD 10647, HD 104860, η Crv, Vega, and β Tri) excluded.

In Figure 8.3 the three resolved discs are put onto the Γ -plot of pure astrosilicate, where in addition the confidence levels of $\Gamma(L)$ are given. HD 107146 as worst estimate is a $\approx 3\sigma$ -outlier and shows that for low stellar luminosities an over- or underestimate up to 60% is possible. In case of more luminous stars the estimate is more accurate. In the literature the blackbody radius is often used as first guess of the disc radius, but as shown above our proposed method of radius estimation is in any account a better way comparing the results of Table 8.2, where e.g., for HD 32297 $R_{\text{BB}} = 26$ AU while $R_{\text{disc}} = 110$ AU.

9 Conclusions and summary

In this work we analysed a sample of 39 debris discs around AFGKM-type stars with the goal of finding correlations between stellar and disc parameters. All discs of the sample are well resolved and therefore, we were able to derive their disc radii with a newly invented method, which made it possible to break the degeneracy between the dust grain size and the location of dust in SED modelling. At time of this writing the sample chosen was the largest of resolved debris discs ever analysed.

The SEDs were fit with two different methods, the modified blackbody approximation (MBB) where the dominant grain size is assumed to be $\lambda_0/(2\pi)$ and the size distribution (SD) where the dominant grain size is given by s_{\min} . Since there is a degeneracy between dust grain size and dust composition as well we were able to break it due to the usage of five different dust compositions, namely pure carbon, pure astrosilicate, mixtures of astrosilicate and ice, astrosilicate and vacuum and astrosilicate and carbon. The results of the analysis are as follows:

Disc radii and radius ratio

A comparison of the results achieved with the above mentioned radius estimation in Chapter 5 and the radius values reported in the literature led to the conclusion that the newly invented method of radius estimation can be applied to all debris discs without constraints to the spectral type or distance to the observer. Even for marginally resolved discs the method led to reasonable results.

The inferred disc radii show a large dispersion over the whole luminosity range of the host stars and we could not find a significant correlation between them and the stellar luminosity. Small disc radii can be found around late- and early type stars as well as large disc radii. Thus, the final shape of a debris disc seems to depend on processes like collisional evolution or sculpting by planets rather than temperature-driven processes which play a more important role during the formation of planetary systems.

Furthermore, we found a decrease of the true to blackbody radius ratio as a function of stellar luminosity. Since the blackbody radius can easily be inferred from the SED the correlation found gives a recipe for the estimation of the true disc radius of unresolved debris discs. With this it is possible to break the degeneracy between the grain size and the dust location.

SED models

We could fit all SEDs with a more or less high goodness of fit for both models (MBB and SD) and found that for statistical analyses of disc temperatures or blackbody radii the fit method only plays a minor role. In terms of grain sizes the MBB method only estimates the dominant particle size, whereas the SD method uses it directly. Therefore, some differences can be found in the correlations, but in general these are robust against both fit methods. For individual discs the fit method is more important since it can make a difference between a one or two component system which was the case for AU Mic for instance.

Dust temperature

We found a systematic increase of the dust temperature with increasing stellar luminosity for both fit methods and for all dust compositions used. The ratio of dust to blackbody temperature decreases towards stars of earlier spectral types which is related to the decrease of the true-to-blackbody-radius ratio with stellar luminosity.

Minimum size of dust grains and grain size ratio

We found a slight increase of the minimum grain size with increasing stellar luminosity, but the assumption of a constant grain size with $s_{\min} \approx (5 \pm 3) \mu\text{m}$ is also reasonable. However, theory predicts an even stronger increase of the minimum grain size since the radiation pressure becomes stronger towards more luminous stars. Caused by this small increase, the minimum-to-blowout-grain-size ratio shows a decrease with increasing stellar luminosity. This was the strongest correlation found in this work and it is robust against the variation of dust composition and porosity. It flattens for a higher degree of porosity, but cannot be erased, which was shown by the usage of a 90% porosity composition. The fit results using this extreme composition were unrealistical and the χ^2 -values for the SED fit were quite large, so that there was no way in eradicating the grain size ratio trend.

We used subsamples in order to check whether the grain size ratio trend shows a different shape for different disc parameters and investigated therefore discs with lower and higher fractional luminosity, smaller and larger radii, younger and older ages, lower and higher absolute integrated flux density, lower and higher absolute surface brightness, and marginally and well resolution. Except for lower and higher fractional luminosity and lower and higher absolute integrated flux density the subsamples are statistically indistinguishable in terms of $s_{\min}/s_{\text{blow}}(L)$. The differences for fractional luminosity and absolute integrated flux density seem to be more related to SED fit effects than to physical causes and are related to each other.

Since we could not find technical or statistical reasons for the grain size ratio trend we suppose physical causes for it. Hence, the role of the surface energy constraint on the size of smallest collisional fragments and the role of stirring of dust-producing planetesimals were investigated. The former effect may be responsible for a lack of particles with a small s_{\min}/s_{blow} -ratio in discs around late-type stars, but a recent study showed that the global influence of the surface energy constraint is only of small relevance. On the other hand, the $s_{\min}/s_{\text{blow}}(L)$ trend was confirmed by collisional simulations and thus, the degree of stirring may be related to the grain size ratio trend. A conclusion would be that discs around more luminous stars are more strongly excited than around low-luminosity stars and so the protoplanetary discs of more massive young stars may be more efficient in building large planetesimals or planets which act as stirrers at later evolutionary stages.

Both explanations, the microphysical (surface energy) and the macrophysical (stirring) one are related to each other, since they involve small grain dynamics which is set by radiation pressure. Hence, a combination of both could be done in future work in order to improve the analysis of the $s_{\min}/s_{\text{blow}}(L)$ trend.

It might be also possible that alternative explanations for this trend exist. Several fit parameters of the disc, e.g., chemical composition, tensile strength or degree of porosity, could vary with the type of central star, but up to now, there is no observational evidence for such correlations and theoretical expectations do not support this assumption as well. An example are the progenitors of debris discs around early and late-type stars, Herbig Ae/Be stars and T Tau stars. The dust compositions of their cold disc parts show no evidence for systematic differences (e.g., Dutrey et al., 2014).

Size distribution index

The opacity index of the MBB model shows values between 0.3 and 2.0 for the whole sample of resolved debris discs which confirms previous determinations based on sub-mm data. Considering the SD method, the values of the index q lie between 3.0 and 4.5 for most of the debris discs using pure astrosilicate, but there are more extreme values as well (η Crv: $q = 2.9$ and 30 Mon: $q = 6.6$). Considering other dust compositions the variation of q is only minor. In general, q is roughly consistent with results from detailed collisional modelling, but there it changes with the particle size, whereas in the SD method only one q is used for the whole grain size range. Therefore, differences between the results of collisional modelling and SD method are evident.

Dust composition

As mentioned before, the correlations found between disc and stellar parameters are robust against the variation of the dust composition not considering extreme porosity. An extreme mixture of 90% vacuum and 10% astrosilicate led to large χ^2 values in the SED fits and gave unrealistical fit results. Therefore, no conclusions can be made in this case.

On the other hand, the dust composition is important for the modelling of individual systems. Here, astrosilicate was used as a kind of “reference material” for all discs, but it is not the best choice since it is a designed material for the description of observations of the interstellar medium (Draine and Lee, 1984). As such it does not exist in nature and has no justification for the application to circumstellar discs may it a protoplanetary or a debris one. The modelling of individual systems shows that pure astrosilicate fits SEDs more poorly than combinations with ice, carbon and vacuum (e.g., Lebreton et al., 2012; Donaldson et al., 2013; Morales et al., 2013; Schüppler et al., 2014, among many others).

Summary and outlook

One general conclusion of this thesis is that the statistical modelling of debris discs is not as easy as it seems, since each disc is an individual system with its own peculiarities. An example is the star β Tri, which possesses the highest stellar luminosity in the sample, is one of only two giants and a close binary as well. Nevertheless, all these individuals seem to follow general trends, that are robust against the variations of fit method or dust composition.

With 39 well-resolved debris discs the sample chosen for this analysis can be increased by several other resolved discs in future works in order to make the correlations found even more robust. It is also possible to derive an improved “reference material” as dust composition for debris discs, leading to more reliable results in SED fitting of individual discs. Furthermore, the investigation of correlations of a sample of collisionally modelled discs would be interesting. At time of this writing, HIP 17439, AU Mic, HD 207129, q^1 Eri and Vega were modelled with the collisional code ACE, but in the future more discs will be done.

Notes:

All values and error bars are taken from the literature as they were published. For instance, *WISE* error bars for different objects may or may not include the calibration uncertainty. (1) For these stars, more photometry points extracted from the IRS spectra have been published. Although not given in the table, these were included in the SED fitting. (2) For these stars, we took the IRS spectra from CASSIS (Lebouteiller et al., 2011). The spectra of objects taken in mapping mode were reduced as in Moór et al. (2013a,b). For those observed in low-resolution staring mode we made additional steps (outlier detection, module stitching) as described in Moor et al. (in prep.). In both cases, we then took averages in the wavelength ranges 15–17, 21–23, and 30–32 microns to extract the photometry points. (3) This object was observed in high resolution staring mode. Since no CASSIS spectrum is available, we used its Spitzer Science Center IRS Enhanced Product, performed the usual post-processing steps, and then extracted the photometry points. (4) For these stars, IRS spectra in different observing modes have been taken (Lebreton et al., 2013; Su et al., 2013b; Chen et al., 2014; Duchêne et al., 2014). However, the resulting fluxes are not given in the literature, except for two photometry points for HD 216956. We decided not to reduce the data by ourselves because of the large spatial extent and brightness of the objects (saturation effects). *Instruments:* (a) *Spitzer*/IRS; (b) *WISE*; (c) *AKARI*; (d) *Spitzer*/MIPS.

Notes:

All values and error bars are taken from the literature as they were published. This explains, for instance, why non-detections are sometimes given as measured values (4.2 ± 4.9) and sometimes as upper limits (< 15.0).

Instruments:

(a) *Spitzer*/MIPS; (b) *Herschel*/PACS; (c) *Herschel*/SPIRE; (d) JCMT/SCUBA; (e) APEX/LABOCA.

Notes:

(1) The disc radii are given in AU, the temperatures in K and s_{min} , s_{blow} in μm and the fractional luminosity in 10^{-5} . (2) For the values of s_{blow} the equation of Burns et al. (1979) (see Equation (2.16)) was used with a material density of $\varrho = 2.25 \text{ g/cm}^3$. Q_{pr} was averaged over the stellar spectrum. (3) The warm component is treated as blackbody. Therefore, the given R_{disc} and T_{d} are blackbody radius or temperature, respectively.

B.2 Astrosilicate and Vacuum

B.2.1 50% Astrosilicate and 50% Vacuum

Notes:

(1) The disc radii are given in AU, the temperatures in K and s_{min} , s_{blow} in μm and the fractional luminosity in 10^{-5} . (2) For the values of s_{blow} the equation of Burns et al. (1979) (see Equation (2.16)) was used with a material density of $\rho = 1.65 \text{ g/cm}^3$. Q_{pr} was averaged over the stellar spectrum. (3) The warm component is treated as blackbody. Therefore, the given R_{disc} and T_d are blackbody radius or temperature, respectively.

Notes:

(1) The disc radii are given in AU, the temperatures in K and s_{min} , s_{blow} in μm and the fractional luminosity in 10^{-5} . (2) For the values of s_{blow} the equation of Burns et al. (1979) (see Equation (2.16)) was used with a material density of $\varrho = 1.95 \text{ g/cm}^3$. Q_{pr} was averaged over the stellar spectrum. (3) The warm component is treated as blackbody. Therefore, the given R_{disc} and T_{d} are blackbody radius or temperature, respectively.

Table C.1: Resolved debris discs sorted by HD number. Column SpT gives the spectral type, d the distance to the observer and Vmag the apparent magnitude in the V band. We used values from SIMBAD (<http://simbad.u-strasbg.fr/simbad/sim-fid>). Spatially resolution of the discs is reported in the literature cited under Reference.

Ehrenwörtliche Erklärung

Ich erkläre hiermit ehrenwörtlich, dass ich die vorliegende Arbeit selbstständig, ohne unzulässige Hilfe Dritter und ohne Benutzung anderer als der angegebenen Hilfsmittel und Literatur angefertigt habe. Die aus anderen Quellen direkt oder indirekt übernommenen Daten und Konzepte sind unter der Angabe der Quellen gekennzeichnet.

Bei der Auswahl und Auswertung folgenden Materials haben mir die nachstehend aufgeführten Personen in der jeweils beschriebenen Weise unentgeltlich geholfen:

1. Prof. Dr. Alexander Krivov
2. Dr. Jonathan P. Marshall
3. Dr. Benjamin Montesinos
4. Dr. Steve Ertel

Weitere Personen waren an der inhaltlich-materiellen Erstellung der vorliegenden Arbeit nicht beteiligt. Insbesondere habe ich hierfür nicht die entgeltliche Hilfe von Vermittlungs- bzw. Beratungsdiensten (Promotionsberater oder andere Personen) in Anspruch genommen. Niemand hat von mir unmittelbar oder mittelbar geldwertige Leistungen für die Arbeiten erhalten, die im Zusammenhang mit dem Inhalt der vorgelegten Dissertation stehen.

Die Arbeit wurde bisher weder im In- noch im Ausland in gleicher oder ähnlicher Form einer anderen Prüfungsbehörde vorgelegt.

Die geltende Promotionsordnung der Physikalisch-Astronomischen Fakultät ist mir bekannt. Ich versichere ehrenwörtlich, dass ich nach bestem Wissen die reine Wahrheit gesagt und nichts verschwiegen habe.

Jena, den

Nicole Pawellek

Lebenslauf

Zur Person

Name: Nicole Pawellek
Geburtsdatum: 06. Dezember 1988
Geburtsort: Meiningen/Thüringen
Staatsangehörigkeit: Deutsch

Werdegang

1995 – 1999: Grundschule in Meiningen/Thüringen
1999 – 2003: Gymnasium in Meiningen/Thüringen
2003 – 2007: Gymnasium mit mathematisch-naturwissenschaftlichen Spezialklassen
Ilmenau/Thüringen
20.06.2007 Allgemeine Hochschulreife (Abitur) mit
besonderer Leistungsüberprüfung für Spezialklassen (Spezialklassenabitur)
2007 – 2010 Studium der Physik an der Friedrich-Schiller-Universität Jena
(Abschluss: Bachelor of science)
2010 – 2012 Studium der Physik an der Friedrich-Schiller-Universität Jena
(Abschluss: Master of science)
2011 Teilnahme an der Sommerschule der ESA mit dem Thema
“Star formation across the universe”
seit 01.10.2012 Graduiertenstudium an der Friedrich-Schiller-Universität Jena
als wiss. Mitarbeiterin am AIU unter Betreuung durch Prof. A.V. Krivov
2013 – 2014 Betreuung von Studenten als Assistentin im Physikalischen Grundpraktikum
2014 – 2015 Leitung der Übung zur Vorlesung “Einführung in die Radioastronomie”
